Abstract

Background: BRCA1 and, more commonly, BRCA2 mutations are associated with increased risk of male breast cancer (MBC). However, only a paucity of data exists on the pathology of breast cancers (BCs) in men with BRCA1/2 mutations. Using the largest available dataset, we determined whether MBCs arising in BRCA1/2 mutation carriers display specific pathologic features and whether these features differ from those of BRCA1/2 female BCs (FBCs).

Methods: We characterised the pathologic features of 419 BRCA1/2 MBCs and, using logistic regression analysis, contrasted those with data from 9675 BRCA1/2 FBCs and with population-based data from 6351 MBCs in the Surveillance, Epidemiology, and End Results (SEER) database.

Results: Among BRCA2 MBCs, grade significantly decreased with increasing age at diagnosis (P = 0.005). Compared with BRCA2 FBCs, BRCA2 MBCs were of significantly higher stage (P for trend = 2 × 10−5) and higher grade (P for trend = 0.005) and were more likely to be oestrogen receptor–positive (odds ratio (OR) 10.59; 95% confidence interval (CI) 5.15–21.80) and progesterone receptor–positive (OR 5.04; 95% CI 3.17–8.04). With the exception of grade, similar patterns of associations emerged when we compared BRCA1 MBCs and FBCs. BRCA2 MBCs also presented with higher grade than MBCs from the SEER database (P for trend = 4 × 10−12).

Conclusions: On the basis of the largest series analysed to date, our results show that BRCA1/2 MBCs display distinct pathologic characteristics compared with BRCA1/2 FBCs, and we identified a specific BRCA2-associated MBC phenotype characterised by a variable suggesting greater biological aggressiveness (i.e., high histologic grade). These findings could lead to the development of gender-specific risk prediction models and guide clinical strategies appropriate for MBC management.

Keywords: Male breast cancer, BRCA1/2, Pathology, Histologic grade, Genotype–phenotype correlations

Background

Male breast cancer (MBC) is a rare disease. It accounts for less than 1% of all breast cancers and less than 1% of all cancers in men. The annual incidence is estimated at about 1 per 100,000 men worldwide [1], and lifetime risk is less than 1 in 1000. Incidence rates for MBC increase linearly and steadily with age, with the mean age at diagnosis being between 60 and 70 years [2]. Family history of breast cancer is an important risk factor for developing MBC, suggesting the importance of genetic factors in MBC susceptibility [3, 4]. Mutations in the two major high-penetrance breast cancer genes, BRCA1 (breast cancer 1, early onset gene) and predominantly BRCA2 (breast cancer 2, early onset gene), account for approximately 10% of MBCs outside populations with BRCA founder mutations [5]. The lifetime risk of developing MBC has been estimated to be in the range of 1–5% for BRCA1 and 5–10% for BRCA2 mutation carriers, compared with a risk of 0.1% in the general population [6–9].

MBC is recognised as being a hormone-dependent malignancy, and it is widely accepted as an oestrogen-driven disease, specifically related to hyperestrogenism [10]. In the general population, MBC is similar to late-onset, post-menopausal, oestrogen receptor−/progesterone receptor−positive (ER+/PR+) female breast cancer (FBC). However, compared with FBC, MBC has been reported to occur later in life, present at a higher stage and display lower histologic grade, with a higher proportion of ER+ and PR+ tumours [11].

There is increasing evidence suggesting that MBC may be a group of molecularly and clinically heterogeneous malignancies which differ from those seen in women [12]. It is well known that breast cancer in women is a heterogeneous disease. Breast cancers arising in female BRCA1 mutation carriers display characteristic pathologic features, including distinct morphology (i.e., carcinomas with medullary features) and a triple-negative phenotype (i.e., ER−, PR−, human epidermal growth factor receptor 2−negative (HER2−)) in the majority. In contrast, BRCA2 breast tumours are a more heterogeneous group, being broadly similar to non-BRCA−associated breast tumours, which more closely resemble post-menopausal FBCs, although with a tendency to be of high grade and HER2− [13].

Current knowledge of the pathologic characteristics of breast cancers arising in male BRCA1/2 mutation carriers is limited, owing to the small number of carriers included in individual studies [14–17]. In a study including 50 male BRCA1/2 mutation carriers, it was suggested that BRCA2 MBCs may represent a subgroup of tumours with a peculiar phenotype not identified in FBC and characterised by an aggressive biological behaviour [16]. Furthermore, in a study including 28 male BRCA1/2 mutation carriers, a possible BRCA2 phenotype characterised by micropapillary histology was suggested [17]. In other, smaller studies, BRCA2 MBCs were associated with younger age at diagnosis and positive lymph node status [14, 15].
In this study, we report pathology data characteristics of 419 BRCA1/2 MBCs derived from the Consortium of Investigators of Modifiers of BRCA1/2 (CIMBA), who conducted the largest study of its kind to date. The main objective of our study was to characterise the pathologic features of BRCA1/2 MBCs and contrast those with the characteristics of BRCA1/2 FBCs, as well as with MBCs in the general population.

Methods
CIMBA study participants
CIMBA collects data on male and female BRCA1 or BRCA2 pathogenic mutation carriers older than 18 years of age, with the majority recruited through cancer genetics clinics [18]. CIMBA data were submitted by 55 study groups in 24 countries based in Europe, North America and Australia. Pathology data from MBC cases for the present analysis were collected by 35 study groups (Additional file 1). Key variables collected for all CIMBA patients include year of birth, age at cancer diagnosis (breast, ovarian or prostate cancers), age at last observation, family membership, race and/or ethnicity and information on applicable prophylactic surgeries. This work was restricted to male and female mutation carriers who had been diagnosed with breast cancer and were of self-reported European ancestry. The number of male mutation carriers of non-European ancestry (2 BRCA1 and 20 BRCA2) was too small to allow a meaningful analysis. These subjects were excluded from the analysis.

A signed informed consent form was obtained from study participants. All participating studies were approved by local ethical review committees (Additional file 2).

Tumour pathology data
MBC pathology data were obtained from a range of sources, namely medical, pathology or tumour registry records and immunohistochemical staining and/or scoring of tissue microarrays (TMAs) (Additional file 3). The data included information on ER, PR and HER2 status; morphological subtype; lymph node involvement; TNM (tumour, node, metastasis) staging and histologic grade. For ER, PR and HER2, status was classified as negative or positive. The vast majority of centres employed a cut-off of either ≥10 % or ≥1 % of tumour nuclei staining positive to define ER/PR receptor positivity, which was not centrally reclassified, owing to the low proportion of records with supporting staining data (Additional file 3). HER2 status was determined using immunohistochemistry (IHC) to detect strong complete membrane staining (with 3+ considered positive) with in situ hybridisation to detect HER2 gene amplification in equivocal cases. Consistency checks were performed to validate receptor data against supplementary scoring information when provided. Central pathology review was not performed.

Each carcinoma was assigned to a morphologic subgroup (ductal, lobular, medullary, other), which was confirmed using the World Health Organisation International Classification of Diseases 0 code for the classification of tumour type when present. Lymph node status, along with the number of nodes showing metastatic carcinoma, was provided when available. Staging data were based on the AJCC Cancer Staging Manual, Sixth Edition [19], with data provided on overall stage and its major attributes (primary tumour size, regional lymph node involvement and presence of distant metastasis). Histologic grade was determined by local pathologists using modifications of the Scarff-Bloom-Richardson histological grading system as grade 1, 2 or 3. Pathology data for FBCs included in the study are described in detail elsewhere [13].

SEER data
We obtained MBC pathology data from the SEER 18 Registries Database for cases diagnosed from 1973 to 2011 [20]. For this study, we selected only male Caucasian cases diagnosed with invasive breast cancer. For SEER cases, pathology characteristics included age at diagnosis; morphologic subgroup; tumour grade; lymph node status; adjusted stage based on the AJCC Cancer Staging Manual, Sixth Edition [19]; ER, PR and HER2 status. Tumour grade was classified as grade 1 (well differentiated), grade 2 (moderately differentiated) or grade 3 (poorly differentiated).

SEER includes unselected MBCs, most of which are of unknown BRCA1/2 mutation status. On the basis of published data [3, 21, 22], about 10 % of MBC cases are expected to be due to BRCA1 or BRCA2 mutations.

Statistical methods
Logistic regression was used to assess the association between pathologic characteristics and male BRCA1/2 mutation carrier status, as well as to compare pathologic characteristics with data from female BRCA1/2 mutation carriers and from male breast tumours arising in the general population using SEER data. In the logistic regression analysis, each pathologic characteristic was treated as the explanatory variable. The outcome variables were BRCA mutation status (BRCA1/BRCA2), sex (female/male) and carrier status (general population/BRCA1 mutation carrier and general population/BRCA2 mutation carrier), with the first term used as the reference group. For assessment of continuous or ordered variables, such as age at diagnosis, stage and grade, tests for trend were also performed.

Analyses within CIMBA data were adjusted for age at diagnosis and country of origin, whereas comparisons between CIMBA and SEER data were adjusted only for age at diagnosis. In addition, an adjustment for calendar year of diagnosis was included in all analyses, based on
the following groupings: up to 1990, 1991–2000 and after 2000. A robust variance approach was used to allow for dependencies between related individuals. All analyses were carried out using Stata v13 software (StataCorp, College Station, TX, USA).

Results
Pathologic characteristics of MBC in BRCA1 and BRCA2 mutation carriers
Information was available for 419 MBC cases, including 375 BRCA2 and 44 BRCA1 mutation carriers (Additional file 1). Median age at MBC diagnosis was 62 years [interquartile range (IQR) 16] for BRCA2 mutation carriers and 62 years (IQR 18) for BRCA1 mutation carriers.

The analysis was restricted to carriers diagnosed with invasive breast cancer (326 BRCA2 and 40 BRCA1) (Additional file 4). The majority of tumours were invasive ductal carcinoma in both BRCA2 (95.1%) and BRCA1 (100%) carriers. Among tumours with data on stage and grade, the majority of BRCA2 mutation carriers presented with stage 2 disease (47%) and tumours of histologic grade 3 (56.7%), whereas the majority of BRCA1 mutation carriers presented with stage 3–4 disease (42.9%) and histologic grade 3 tumours (69.2%). Among tumours with ER, PR and HER2 data, 96.7% were ER+, 86.8% were PR+ and 83.4% were HER2– in BRCA2 mutation carriers, vs. 90.3% ER+, 78.6% PR+ and 89.5% HER2– in BRCA1 mutation carriers.

Age at diagnosis was inversely associated with grade in BRCA2 mutation carriers (grade 1/2 vs. grade 3, \( P = 0.005 \)), with no evidence for differences in ER, PR and HER2 distributions by age (test for differences \( P > 0.05 \) for all) (Fig. 1). Furthermore, there was no evidence of association between grade and ER or PR status (\( P \) values for trend = 0.50 and 0.78, respectively). For BRCA1 mutation carriers, no differences in age-specific proportions of tumours by grade or ER, PR and HER2 status were observed, but their numbers were small (data not shown).

When we compared the pathologic characteristics of MBC in BRCA1 and BRCA2 mutation carriers, we observed no statistically significant differences. However, tumours in BRCA1 mutation carriers were more likely to

present with more advanced stage (42.9 % vs. 23.5 %, \( P \) for trend = 0.11) and were more frequently ER− (9.7 % vs. 3.3 %, \( P = 0.17 \)) and PR− (21.4 % vs. 13.2 %, \( P = 0.27 \)) than tumours in \( BRCA2 \) mutation carriers (Additional file 4).

**Characterisation of \( BRCA2 \) MBCs: comparison with \( BRCA2 \) FBC and with MBC in the general population**

We evaluated possible pathologic differences between invasive breast cancers arising in male and female \( BRCA2 \) mutation carriers by comparing available data from female mutation carriers with breast cancer in the CIMBA dataset. Data from 3750 country-matched female \( BRCA2 \) mutation carriers diagnosed with invasive breast cancer were included in this analysis (Table 1). The results revealed that there were significantly fewer invasive lobular carcinomas among male \( BRCA2 \) mutation carriers than among female \( BRCA2 \) mutation carriers [odds ratio (OR) 0.14, 95 % confidence interval (CI) 0.05–0.43]. In addition,

**BRCA2** breast cancer 2, early onset gene, CI confidence interval, ER oestrogen receptor, HER2 human epidermal growth factor receptor 2, OR odds ratio, PR progesterone receptor, TNM tumour, node, metastasis

Significant results are indicated by boldface type

\( ^a \)Analyses adjusted for country, age at diagnosis and calendar year of diagnosis

\( ^b \)Some data for each pathologic feature are not available
compared with BRCA2 FBCs, BRCA2 MBCs were of significantly higher stage ($P$ for trend = $2.14 \times 10^{-5}$) and higher grade ($P$ for trend = 0.005), presented more frequently with lymph node involvement (OR 1.55, 95% CI 1.12–2.14) and were more likely to be ER+ (OR 10.59, 95% CI 5.15–21.80), PR+ (OR 5.04; 95% CI 3.17–8.04) and non–triple-negative (OR 0.05, 95% CI 0.01–0.22). Associations with stage and nodal, ER and PR status remained significant after adjustment for grade.

We then compared pathologic features of MBC arising in BRCA2 mutation carriers with characteristics of MBC in the general U.S. population as represented by SEER. We extracted pathology data of 6351 men with invasive breast cancer from the SEER 18 database. There were no statistically significant differences in pathology characteristics between MBCs arising in BRCA2 mutation carriers and those arising in the general population, with the exception of grade and lymph node status (Table 2).

BRCA2 breast cancer 2, early onset gene, CI confidence interval, ER oestrogen receptor, HER2 human epidermal growth factor receptor 2, OR odds ratio, PR progesterone receptor, TNM tumour, node, metastasis

*Significant results are indicated by boldface type

*Analyses adjusted for age at diagnosis and calendar year of diagnosis

*Some data for each pathologic feature are not available
Male BRCA2 mutation carriers more frequently had grades 2 and 3 tumours than grade 1 tumours, as compared with MBC cases from the general population (grade 2 vs. grade 1 OR 2.98, 95% CI 1.44–6.19; grade 3 vs. grade 1 OR 5.53, 95% CI 2.69–11.39; \( P \) for trend = 4.52 × 10^{-12}). Moreover, BRCA2 mutation carriers presented more frequently with lymph node involvement than MBC cases from the general population, a difference that was not significant when adjusted for age at diagnosis and/or grade.

Characterisation of BRCA1 MBCs: comparison with BRCA1 FBC and with MBC in the general population

A total of 5925 country-matched female BRCA1 mutation carriers diagnosed with invasive breast cancer were compared with our BRCA1 MBC series, which revealed that MBCs were of significantly higher stage (stage 3–4 vs. stage 1 OR 17.59, 95% CI 3.47–89.03; \( P \) for trend = 0.001) and presented more frequently with lymph node involvement (OR 2.19, 95% CI 1.03–4.65) than FBCs in BRCA1 mutation carriers (Additional file 5). The association with stage remained significant after adjusting for ER and PR status. Moreover, BRCA1 MBCs were more likely to be ER+ (OR 20.22, 95% CI 5.91–69.17), PR+ (OR 13.76, 95% CI 5.31–35.67) and non–triple-negative (OR 0.03, 95% CI 0.00–0.25). The associations with ER and PR status remained significant after adjustment for age. There was no statistically significant difference in the distribution of histologic grade among male and female BRCA1 breast cancers.

The comparison between MBCs arising in BRCA1 mutation carriers with those of 6351 MBCs from the SEER database showed no significant differences in pathologic characteristics (Additional file 6). However, BRCA1 male breast tumours trended toward higher grade compared with those in the general population (\( P \) for trend = 0.003).

Discussion

To date, most of the available knowledge on MBC is based on MBC arising in the general population, whose BRCA1/2 mutation status is largely unknown. In this study, we sought to determine whether MBC arising in BRCA1 and BRCA2 mutation carriers displayed specific pathologic characteristics. We used data on 419 MBCs with BRCA1 and BRCA2 mutations from an international consortium (CIMBA). The CIMBA series represents the largest collection of MBCs arising in BRCA1 and BRCA2 mutation carriers to date. In our series, the majority of MBC cases (375 of 419, 89.5%) were BRCA2 mutation carriers, a finding which corroborates prior, smaller studies.

In this study, we conducted the first comparison of the pathologic features of breast cancer arising in male and female BRCA1/2 mutation carriers, taking advantage of the previously collected pathology data from female BRCA1/2 mutation carriers assembled by CIMBA [13].

We found that breast cancer in male BRCA2 mutation carriers was of significantly higher stage and histologic grade, and was more frequently ER+ and PR+, than breast cancer in female BRCA2 mutation carriers. Advanced stage disease at breast cancer diagnosis is more frequently observed in men than in women [23]. In general, this is thought to reflect diagnostic delay in a population unaware of its risk and (appropriately) not encouraged to undergo routine breast cancer screening. Furthermore, although breast cancer primaries in men tend to be slightly smaller than those in women when they are first diagnosed, they more often have locoregional metastasis at presentation. Indeed, we found that male BRCA2 mutation carriers presented more frequently with lymph node involvement than breast cancer in female mutation carriers.

It is known that MBC presents with lower histologic grade tumours than FBC in the general population [11]. In contrast, in the present study, we showed that MBC associated with BRCA1 mutations presents with higher histologic grade than both breast cancer in female BRCA2 mutation carriers and MBC in the general population from SEER.

We observed that the majority of BRCA2 MBCs are of grades 2 and 3. However, grade 3 tumours were more frequent among male BRCA2 mutation carriers diagnosed at younger ages (younger than age 50 years) than among those diagnosed at older ages, whereas grade 2 tumours showed an inverse trend. Age-specific proportions of MBCs stratified by grade show that grade 3 significantly decreased with increasing age in male BRCA2 mutation carriers. These results may indicate that young male BRCA2 mutation carriers could be susceptible to more aggressive (i.e., high-grade) breast cancer. Differences in grade among male breast carcinomas by age may be an indicator of a biologic complexity in MBC, as suggested in FBC [24].

In a previous, single-country case series, MBCs associated with BRCA2 mutations were found to be of higher grade than non-BRCA2 MBC [16]. In the present study, we confirmed this association in a large, multicentre series and showed that this association was age-specific. The identification of a specific BRCA2-associated phenotype suggestive of an aggressive behaviour might define a subset of MBC patients (i.e., patients with high-grade breast tumours and with young age at diagnosis) who may particularly benefit from adjuvant chemotherapy [2, 25].

We also showed that high-grade breast tumours were more likely to arise in male than in female BRCA2 mutation carriers, indicating that BRCA2 mutations might be associated with different breast cancer phenotypes in men and in women. It has been suggested that high grade is a surrogate for proliferation, and, although the evidence is conflicting, this may add to the understanding of the molecular differences of MBC and FBC.
MBC is recognised as being primarily a hormone-dependent malignancy, and, in general, MBC is described as being more frequently ER+ and PR+ than FBC [10, 11, 23]. In the present study, we showed that BRCA2 MBCs are more likely than BRCA2 FBCs to be ER+ and PR+, thus suggesting that susceptibility to hereditary breast cancer may be influenced by differences in hormonal background between male and female BRCA2 mutation carriers.

Invasive lobular carcinomas are very rare in men, accounting for only about 2% of all MBCs [23, 26]. We also found significantly fewer lobular carcinomas among male than female BRCA2 mutation carriers. However, it is worth noting that breast cancers in female BRCA2 mutation carriers frequently show a lobular morphology [13], thus suggesting differences in the pathogenic mechanisms of male and female BRCA2 breast cancer.

The number of MBC cases with BRCA1 mutations in our datasets was much smaller than the number of BRCA2 mutation carriers, and our results in this subset of patients should therefore be interpreted with caution. We found that BRCA1 MBC cases were of significantly higher stage, and more frequently ER+ and PR+, than BRCA1 FBCs. Despite the small sample size, our results suggest that hormone receptor pathways also are a driving force in BRCA1 MBC. It is well known that most of the breast tumours arising in female BRCA1 mutation carriers tend to be ER− and PR−, with a small percentage being ER + [13, 27, 28]. Given that both ER− and ER+ BRCA1 breast cancers seem to originate from a common luminal progenitor cell population, it has been suggested that ER status of breast cancer occurring in BRCA1 mutation carriers may be under control of different molecular mechanisms [29]. The finding that MBCs associated with BRCA1 mutations are frequently ER+ suggests that the hormonal milieu may be a mechanism controlling ER status in BRCA1 tumours. The different hormonal background between males and females and the absence of hormone exposures related to reproductive history in males as compared with FBC may also influence biologic and molecular mechanisms underlying the pathologic differences between MBC and FBC. Following the findings in the present study, future studies are warranted which focus on the comprehensive somatic and molecular profiling of MBC and FBC in mutation carriers. Such studies could provide new insights into the complex nature of the origin and evolution of MBC and FBC.

Interestingly, we found no statistically significant differences in the pathologic characteristics between MBCs in BRCA1/2 mutation carriers and those in the general population, with the exception of histologic grade. Male BRCA2 mutation carriers more frequently have grade 2/3 vs. grade 1 tumours, compared with the large, unselected population of MBC cases from SEER. A similar trend also was observed for BRCA1 mutation carriers. These findings suggest that, although MBCs arising in male BRCA1/2 mutation carriers seem to be very similar to MBCs arising in the general population, according to morphologic and immunophenotypic features, they represent a subgroup characterised by aggressive biology.

The importance of histologic grade as a prognostic factor in breast cancer has been ascertained in FBC [30]. Recent data indicate that high-grade tumours are associated with shorter disease-free survival and overall survival rates in MBC patients [25]. Thus, on the basis of our results, we can suggest that BRCA2 MBC may display an aggressive phenotype and possibly a more unfavourable prognosis. This is a question in need of additional survival data that we are planning to collect within CIMBA.

In this study, tumour pathology data were collected through several mechanisms, including medical records, pathology reports and TMAs. Given the global distribution of CIMBA study sites, central pathology review was not feasible. Laboratory methods for tissue preparation, IHC, biochemical assays, scoring systems and data interpretation vary widely (Additional file 3), and misclassifications cannot be excluded. Unfortunately, details of hormone receptor scoring for all mutation carriers were not available to standardise definitions across centres. However, data collected by CIMBA are more representative of typical assessment of pathology conducted in routine practice, and the distributions of hormone receptors’ status across different study centres and countries in CIMBA were generally consistent. There was some variation in the distribution of some variables, including ER status, probably due to changing assay thresholds and detection methods over time and from country to country. Therefore, adjustments based on calendar year of diagnosis and country of origin were included for all analyses. Missing data for some variables, including HER2 status, and the very small number of male BRCA1 mutation carriers in the study may have impacted the statistical power to detect associations.

CIMBA collects data only on BRCA1 and BRCA2 mutation carriers. Therefore, to compare the tumour characteristics of MBC from the general population, we took advantage of the publicly available SEER data [20]. Although the U.S. SEER program is the largest source of epidemiologic information on the incidence and survival rates of cancer, it includes data from a single country, and this represents a limitation when attempting to generalise our findings to what one would expect in a collaborative international consortium. However, results from this study, based on a large, multicentre series, replicated previous findings of much smaller studies carried out in single populations [14–17], providing some reassurance that our results were not biased by the different selection of cases in SEER and in CIMBA. In addition, SEER includes MBCs that were not screened for BRCA1 and BRCA2 mutations, and it can be expected that about
10 % of those cases [3, 21, 22] may be due to BRCA1 or BRCA2 mutations. In future studies, researchers should aim to compare BRCA1/2 MBC cases with those known not to have BRCA1/2 mutations.

Conclusions

Analysing the largest series of BRCA1 and BRCA2 breast cancers collected to date from both sexes, we have demonstrated that breast tumours arising in BRCA1 and BRCA2 mutation carriers display pathologic differences between males and females. Thus, our results add to the accumulating evidence that breast cancer may not be the same disease in both genders [12] and suggest that the heritable influence on breast cancer susceptibility may be context-dependent, perhaps influenced by the microenvironment (i.e., a different hormonal milieu in males and females).

Moreover, we identified a specific BRCA2-associated MBC phenotype characterised by higher histologic grade compared with both BRCA2 FBC and MBC from a general population. This raises the possibility that BRCA2 MBC may be more aggressive than its sporadic counterpart.

Overall, our findings could lead to the eventual development of clinical strategies appropriate for MBC management, and of gender-specific risk prediction models that might guide more targeted screening and surveillance programs for male mutation carriers.
