A great deal of interest in dipolar Fermi gases has been generated due to their long-range interactions, which lead to many novel effects such as \( p \)-wave superfluidity [1–4], topological superfluidity in two-dimensional systems [5,6], anisotropic and many-body effects on the Fermi-liquid properties [7,8], the tailoring of novel interaction potentials [9,10], and superfluidity in bilayers [11,12].

This rich selection of interesting phenomena has led to a large effort from many groups to trap and cool a dipolar gas to degeneracy. Many highly successful experiments have resulted from this effort, which have concentrated on both molecular [13–19] and atomic, highly magnetic dipolar gases [20–27]. These experiments investigated features such as the precise control of ultracold chemical reactions [14–16], quantum chaos in dipolar collisions [22,23], anisotropic interaction effects in the Fermi surface [25], and dipolar collisions [24]. As yet, however, a dipolar Fermi superfluid has not been observed.

Predictions for the superfluid transition temperature of a dipolar Fermi gas \( T_c \) have been calculated in a number of works under various conditions [1,4–6,11,12,28–30]. These works consider a dipolar Fermi gas within an idealized condensed-matter paradigm, which is usually applicable for thermodynamically stable systems. However, an ultracold dilute gas is not stable. We investigate the complications that this introduces and produce our own predictions for \( T_c \) that differ significantly from these previous works at high densities or interaction strengths. After deriving our results, we compare our methodology with previous works in Sec. VI.

This paper will be set out as follows. In Sec. II we review some important theoretical and experimental background involving the stability of \( p \)-wave gases, particularly the collapse into \( p \)-wave dimers. We will then investigate how adding long-range interactions affects these \( p \)-wave dimers and produces dipolar-interaction-dominated bound states. In Sec. III we see that these dipolar bound states can have a large effect on the stability of the gas and therefore also on \( T_c \). A key result of this paper is that we will show that in attempting to renormalize out the short-range behavior of a dipolar gas, previous works in this area have ended up calculating a transition to tightly bound molecules, rather than to a BCS superfluid. We will then suggest a remedy to this problem.

Section IV describes a simple algorithm that allows one to easily calculate the BCS transition temperature for complicated potentials. Furthermore, it allows us to take into account the effect of an anisotropic Fermi surface (in this case caused by the anisotropic interaction potential of a polarized dipolar gas). This is a general algorithm that can be applied to any system. In Sec. V we apply the numerical method from Sec. IV to the theoretical method of Sec. III to obtain prediction for \( T_c \) at different experimental parameters. We find that the region of experimental interest (i.e., high interaction strength or high densities) is where our results differ from previous theoretical works in this area, giving us a \( T_c \) which is much lower. In Sec. VI we will then compare our results to this previous theoretical work in more detail with the aim of understanding how and why they differ.
of the short-range specifics of the potential. The result is that within this regime \[ r_b = \alpha \frac{C_{dd} m}{\hbar^2}, \] (1)

where \( \alpha = 0.6 \) and \( m \) is the mass of the particles. We will use units such that \( r_b = 1, \hbar = 1, k_F = 1, \) and \( m = 1, \) giving units of energy \( E_B = \hbar^2 / m r_b^2 = \hbar^2 / m C_{dd}^2 \). In these units, \( C_{dd} = 1/\alpha \) and \( V_b = 2/3 \) are both constants. All our equations will reduce down to just two dimensionless parameters: the dimensionless temperature \( \tau = T/E \propto T/C_{dd}^2 \), and the dimensionless average distance between atoms \( \lambda = \rho^{-1/3}/r_b \propto C_{dd}^{-1} \), where \( \rho = k_F^3/(6\pi^2) \) is the density and \( k_F \) is the Fermi energy (which gives \( \lambda \approx 3.9/r_b k_F \)). Reference [32] shows, as is verified by experiments [14], that as the average particle kinetic energy approaches \( E_b \), the rate of barrier transmission nears unity, and quenching rates become unacceptably high. We note, as a benchmark for this effect, that the Fermi energy intersects \( V_b \) at \( \lambda \approx 3.38 \).

An important conclusion from Eq. (1) is that in a gas with polarized dipolar interactions, the centrifugal barrier is much farther away from \( r = 0 \) than a gas with short-range interactions. Because dipole interactions are strongly attractive in the \( l = 1, m = 0 \) subspace, they can lead to dipolar bonding between dipoles [33,34]. These dipole-induced, \( p \)-wave dimers will be of the size of the centrifugal barrier and will therefore be much larger than the \( p \)-wave bound states found in typical gases with short-range interactions. The formation of \( p \)-wave dimers is significant because they are well known to be unstable from investigations in systems of identical fermions with short-range interactions near a \( p \)-wave resonance. These systems were first shown to be experimentally unstable [35–44]; then it was then shown that the major cause of this instability could be attributed to the fact that \( p \)-wave dimers, which are formed rapidly via three-body interactions when near the resonance, are unstable to collisional relaxation and decay much faster than they can thermalize [41,45–48]. It has been shown that this behavior is a general property of identical fermions and not of any property of the particular species being investigated [45].

In Fig. 1, we investigate the behavior of a \( p \)-wave dimer of two particles with strong dipolar interaction. The exact details of the interaction potential is species dependent; however, for particles with strong dipolar interactions, which are of interest to us, the largest bound states are dominated by the bare dipolar interaction. We have solved the Schrödinger equation using the finite-element method [49] for a bare dipolar interaction with a cutoff \( R_{cut} \) and plotted the energy and the rms widths of the eigenstates. The short-range behavior is unknown, so we have plotted these eigenstates for a continuously varying value of \( R_{cut} \) (solid and dashed lines), showing the effect that different short-range behaviors can have on the bound states of a dipolar long-range-dominated interaction potential. Figure 1 shows the typical behavior of the bound states, which are evenly spaced and increase in size as \( R_{cut} \) increases. Just before the energy of a bound state crosses zero, the bound state is at its largest, with a rms extent of \( 2.1 r_b \). Just after the energy goes above zero, the bound state disappears, and the next bound state becomes the largest, which is always sitting at around \( 0.15 r_b \). We can therefore conclude that no matter the short-range specifics, the rms size of the largest bound state will be within the range \( 0.15 r_b \) and \( 2.1 r_b \).

Three-body dimerization rates for identical dipolar fermions have been explicitly calculated in [33] but not relaxation rates. In the \( s \)-wave case, the increasing size of a dimer leads to stability against inelastic relaxation collisions as the distance between the shallowest dimer and the deeply bound states increases [45,50–54]. In the dipolar case, the sizes of the deeply bound states increase along with the size of the shallowest dimer, negating that protection. Figure 1 shows that once a weakly bound dimer of two dipoles is formed, there is cascade of nearby tighter bound states that the dimer can easily decay into. These dimers can then be expected to be unstable just as for the short-range case.

III. THE EFFECT OF DIPOLAR BONDING ON \( T_c \)

Here we will show that the formation of these \( p \)-wave dimers is also extremely important for the renormalization of the BCS equations. The BCS equations find the minimum of the free energy. It is well known from the BCS-BEC crossover problem [55] that if the full potential is considered, the BCS equations will simply converge to the tightest bound state and...
form tightly bound bosons. Ultracold gases are metastable, and we are not interested in the absolute ground state. For this reason, the BCS equations are usually renormalized using the method of Randeria et al. [56,57], the purpose being to remove the short-range behavior but capture accurately the long-range scattering properties of the atoms involved. A similar method must be implemented for the case we are interested in: a metastable gas of dipoles that sit outside each other’s centrifugal barriers and interact only via the universal, long-range dipolar interaction.

Predictions for $T_c$ of a dipolar Fermi gas under various conditions have been calculated in a number of works [1,4–6,11,12,28–30]. The most common method used is to introduce the renormalized equations of Randeria et al., except instead of replacing the $T$ matrix with its long-range behavior via a first-order expansion in $k$ (i.e., $4\pi \hbar^2 a/m$), the Born approximation is used to replace the $T$ matrix by the bare potential. However, it is not clear that the short-range behavior is removed with this technique. Indeed, the bare dipolar potential contains all powers of $k$, meaning short-range behavior is merely modified, not removed. In fact, if we examine Fig. 2 in Ref. [1] or Fig. 3(b) in Ref. [30], we can see that, for sufficiently large $k_F$, the gap plotted in those works is the same size and shape as the two-body bound state plotted in the inset in Fig. 1 in this work. For $k_F \approx 0.5/r_b$ ($\lambda \approx 7.8$) the gap in those works is the same size and shape as the largest possible size for the shallowest dimer (solid line in inset in Fig. 1). For $k_F \approx 2.5/r_b$ ($\lambda \approx 1.56$) the gap in those works is the same size and shape as the smallest possible size for the shallowest dimer (dashed line in inset in Fig. 1). A true BCS pairing wave function should be many times the size of the interparticle spacing, not the size of a bound state. This suggests that the BCS equations, renormalized in this way, have simply picked up the tightly bound $p$-wave dimers that we expect to be unstable. In other words, at high densities or interaction strengths, these papers are calculating the transition to a tightly bound Bose-Einstein condensate (BEC) state rather than the desired BCS state.

In this paper we produce our own predictions for a three-dimensional, polarized, dipolar Fermi gas in a way that deals with these issues. We first consider just the case of the KRb experiment at JILA, the solution of which will turn out to be relevant to all systems discussed above. We require a methodology which can describe a situation where the gas is in quasistable equilibrium with molecules sitting outside each other’s centrifugal barriers and, as soon as the particles tunnel, they are almost guaranteed to be lost from the trap. We know that the solutions should be independent of the short-range details of the molecules and should depend only on the $r^{-3}$ dipolar interaction. However, if we were to simply use the bare dipolar interaction, the BCS equations would only pick up the tightly bound states that sit well within the centrifugal barrier and do not represent the metastable equilibrium that is desired.

The problem is that the dipolar interaction becomes very strong inside the centrifugal barrier, but in the KRb experiments at JILA, the molecules in quasistable equilibrium never “feel” that part of the potential, and any particles that do venture within each other’s centrifugal barrier undergo inelastic collisions with close to unit probability [14,32] and, consequently, cannot contribute to the superfluid. We therefore use the following effective potential, which represents the anisotropic interaction between metastable dipoles that are polarized in the $\hat{z}$ direction:

$$V_{\text{dd}}^{\text{(eff)}}(r) = \begin{cases} C_{\text{dd}} \left[ 1 - 3 \cos^2(\theta_r) \right] & r > r_b, \\ 0 & r < r_b, \end{cases}$$

where $C_{\text{dd}}$ is the interaction coupling constant and $\theta_r$ is the angle between $r$ and the $\hat{z}$ axis. Equation (2) is just the usual dipolar potential [58], except cutoff at $r = r_b$. By using Eq. (2), we can minimize the free energy without picking up the undesired bound states, and the dipoles will feel the full dipolar potential outside the centrifugal barrier but not inside, exactly as the molecules in the JILA experiments do. Furthermore, Eq. (2) reproduces the desired universal, dipolar-scattering amplitudes [58,59], which means that provided the short-range contribution to the potential does not put the system on resonance, Eq. (2) contains the key properties desired from a more conventional renormalization method (see the discussion in Sec. V).

IV. NUMERICAL METHOD

We use the following method to find $T_c$, which is generally applicable to any potential and can easily include the effects of the anisotropic exchange interactions. First, recall the standard result that the BCS equations are equivalent to minimizing the BCS free energy $F$ [60]. This free energy can be written in terms of the gap $\Delta(k)$, the potential in momentum space $V(k)$, and the nonsuperfluid part of the quasiparticle energy, $\epsilon(k) = \hbar^2 k^2/2m - \mu + \Sigma(k)$, where $\Sigma$ is the self-energy and includes the Hartree and Fock energies:

$$F = E_0 + E_B - TS,$$

$$E_0 = V \int \frac{d^3k}{(2\pi)^3} \kappa(k) G_k,$$

$$E_B = \frac{V}{2} \int \frac{d^3k}{(2\pi)^3} \int \frac{d^3k'}{(2\pi)^3} J_k V(k,k') J_{k'},$$

$$S = -V \int \frac{d^3k}{(2\pi)^3} f_k \ln(f_k) + (1-f_k) \ln(1-f_k).$$

$$J_k = -\Delta(k) \frac{2}{E(k)} \tanh \left( \frac{E(k)}{2T} \right),$$

$$G_k = \frac{\kappa(k)}{2E(k)} \tanh \left( \frac{E(k)}{2T} \right) + \frac{1}{2},$$

$$\Sigma(k) = \int \frac{d^3q}{(2\pi)^3} \left[ V_{dd}(0) G(q) - V(q-k) G(q) \right].$$

$E(k) = \sqrt{\kappa(k)^2 + \Delta(k)^2}$ is the full quasiparticle energy, $f_k = (1 + e^{E(k)/T})^{-1}$, $V$ is the volume, $V(k) = \int e^{ik \cdot r} V_{\text{dd}}^{\text{(eff)}}(r) d^3r$, $V(k,k') = V(k-k')$, $\kappa(k) = \xi(k)$ + $\Sigma(k)$, $\xi(k) = \epsilon_0(k) - \mu, \epsilon_0(k) = \hbar^2 k^2/2m$,$G_k = (\hat{a}^+_k \hat{a}_k)$, $J_k = (\hat{a}_k \hat{a}^+_k)$, and $f_k = \langle \hat{f}_k \hat{f}_k \rangle$, where $\hat{a}_k^+$ and $\hat{a}_k$ are the creation and annihilation operators of a particle in momentum eigenstate $k$ and $\hat{f}$ is the quasiparticle operator satisfying $\langle \hat{f}_k \hat{f}_k \rangle = 0$, and $\langle \hat{f}_k \rangle = 0$, where $\hat{f}_k = u_k \hat{a}^+_k + v_k \hat{a}_k$ for $c$ numbers $u_k$ and $v_k$.

Note that the BCS transition is a second-order phase transition with order parameter $\Delta$; therefore, it occurs at the point where $\Delta = 0$ goes from being a minimum of the free energy with respect to $\Delta$ to a maximum or saddle point. Hence,
only the Hessian of $F$ with respect to $\Delta$ needs to be calculated. The transition temperature is then simply the point where a negative eigenvalue occurs.

We will also need $V(k)$ in spherical components:

$$V(k,k') = \sum_{l,l'} Y^m_l(\hat{k}) Y^{m'}_{l'}(k') Y^{-m'}_{l'}(\hat{k}),$$

(4)

$$V^m_{ll'}(k,k') = -\frac{(4\pi)^2}{\alpha} \sqrt{\frac{16\pi}{5}} j_l^{\alpha-1}(-1)^m I^m_{ll'} J_{ll'}(k,k'),$$

(5)

$$J_{ll'}(k,k') = \int_1^{\infty} \frac{d r}{r} j_l(k r) j_{l'}(k' r),$$

(6)

$$I^m_{ll'} = \sqrt{\frac{(2l+1)(2l'+1)}{4\pi}} \begin{pmatrix} 1 & 2 & l' \\ 0 & 0 & 0 \end{pmatrix} \begin{pmatrix} m & 0 & -m \end{pmatrix}. $$

(7)

Because we are dealing with identical $p$-wave fermions, we need only consider odd angular momenta $l$. Also, $V^m_{ll'}$ is nonzero only when $l = l'$ or $l' = l \pm 2$ [59]. Notice that the dipolar interactions conserve the angular momentum projection $m$. We will also need the self-energy, which in a polarized dipolar gas is anisotropic and, because the Hartree term is zero, comes from only the exchange interactions, i.e., $-(2\pi)^{-3} \int d^3 q V(q - q) G(q)$. We take $G \approx G_0 = \theta(k F - k)$, where $\theta$ is the Heaviside theta function, which gives

$$\Sigma(k) = -\frac{1}{2\pi} [1 - 3 \cos^2(\theta_k)] \sigma(k),$$

(8)

$$\sigma(k) = \int_1^{\infty} \frac{1}{r^4} [\sin(k_F r) - k_F r \cos(k_F r)] j_{3/2}(k r) d r.$$  

(9)

Notice that $\Sigma$ also conserves the angular momentum projection. In order to solve the problem numerically, we must discretize the radial $k$ direction and choose a maximum angular momentum $l_{\text{max}}$. We define a set of $n+1$ vertices $x_i$, with $i \in [0,n]$, $x_0 = 0$, and $x_n > x_{n-1}$, then we consider only the set of $A(k)$ functions that are constant when $k$ lies between vertices. We also discretize $V(k)$ on this grid. That is, we let

$$A(k) \rightarrow \sum_{l=0}^{l_{\text{max}}} \sum_{m=0}^{l_{\text{max}}} A^m_l(k) U^m_{l,j}(k),$$

(10a)

$$V^m_{ll'}(i,j) \equiv V^m_{ll'}(x_{i+1/2} + x_{j-1/2}, x_{i+1/2} - x_{j-1/2}),$$

(10b)

$$U^m_{l,j}(k) \rightarrow \sum_{i=0}^{n} \sum_{j=1}^{n} U^m_{l,j}(k) V^m_{ll'}(i,j) U^m_{l,j'}(k'),$$

(10c)

$$U^m_{l,j}(k) \equiv \begin{cases} 1 & \text{if } k \in [x_{j-1}, x_j], \\ 0 & \text{otherwise.} \end{cases}$$

(10d)

We now use these discrete forms and Eq. (9) to calculate the free energy $F$. Then, we take the double derivative of $F$ with respect to $\Delta$. Much cancellation occurs, giving the following surprisingly simple result for the discretized Hessian matrix $\mathcal{H}$ of $F$ with respect to the spherical components of the gap:

$$\mathcal{H}^{m'}_{ll'} = \frac{\partial^2 F}{\partial A^m_l(i) \partial A^{m'}_{l'}(j)_{\Delta_0=0}} \frac{V_{ll'}(k,k')}{2(2\pi)^3} \times \left\{ K_{ll'}^{m'}(i) \delta_{i,j} + \frac{1}{(2\pi)^3} \sum_{l,l'} K_{ll'}^{m'}(i) V_{ll'}^{m'}(i,j) K_{ll'}^{m'}(j) \right\}_{\Delta_0=0},$$

(11)

where the $K$ matrix is given by

$$K_{ll'}^{m'}(i) \equiv \int d \bf{k} K(i,\bf{k}) Y_l^m(\bf{k}) Y_{l'}^{m'}(\bf{k}).$$

(12)

$$K(i,\bf{k}) \equiv \int_0^{\infty} \frac{d k}{2 k^2} \tanh \left( \frac{\sqrt{10} k}{2 k_F} \right).$$

(13)

Calculating whether the gas will be superfluid at a certain temperature and density requires only the calculation of the $K$ and $V$ matrices and then finding the lowest eigenvalue of the term inside the brackets in Eq. (11).

This method is applicable to any Hamiltonian for a homogeneous gas. The only difficult numerics arise from calculating the $K$ matrix and a $\int_1^{\infty} \frac{d k}{2 k^2} j_l(k r) j_{l'}(k' r)$ integral that appears in $V^m_{ll'}$. The integral (with perhaps a different power of $r$) is common to any potential, as is the whole $K$ matrix, and it turns out that analytic solutions exist for both these functions that are valid for most points on the grid. This means the Hessian can be calculated easily and efficiently. Details are given in the Appendix.

V. NUMERICAL RESULTS

Results using this methodology for $T_c$, including the effect of anisotropic exchange interactions, are shown in Fig. 2. We use $l = 1$ and $l = 3$ contributions; $l = 5$ makes almost no difference to $T_c$. Also shown is the previous calculation from Ref. [1]. Our inclusion of $l = 3$ states as well as exchange interactions gives us a slightly higher $T_c$ at low densities. At

FIG. 2. Predictions for $T_c$ in a dipolar Fermi gas. $\lambda$ is the dimensionless average distance between dopines given by $(6\pi^2)^{1/3}/(k_F c \alpha C_{\text{int}} n^{1/2})$. The straight line at the top is the position of the Fermi energy, $T = T_F$. The solid blue line is our full numeric calculation. The dashed red line is the theoretical prediction given in Ref. [1]. The markers are the locations of current experiments: $^{40}\text{K}^{87}\text{Rb}$ [14] at the theoretical maximum polarization (open triangle), $^{40}\text{K}^{87}\text{Rb}$ [14] at current experimental polarizations (open circle), $^{23}\text{Na}^{86}\text{K}$ [19] at the theoretical maximum polarization (solid triangle), $^{151}\text{Dy}$ [20] (open diamond), and $^{167}\text{Er}$ [21] (solid diamond); $^{53}\text{Cr}$ [26] is not plotted as it sits too far off to the right. Inset: $T_c$ vs $\lambda$ zoomed in at the peak in $T_c$. The bottom two red lines are with just $l = 1$. The top two blue lines are with $l = 1, 3$. The dashed lines are the results with exchange interactions switched off. The solid blue line in the inset corresponds to the solid blue line in the main plot.
higher densities, the drop in $T_c$ reflects the fact that Ref. [1] is picking up contributions from $p$-wave dimers as discussed above. The inset shows the effect of just considering $l = 1$ and the effect of turning off exchange interactions, which demonstrates that exchange interactions can either increase or decrease $T_c$ depending on the circumstances.

But what about the case of dipolar molecules that are chemically stable against two-body collision [61], such as $^{23}\text{Na}^{40}\text{K}$ [17,19], or dipolar atoms? In a typical gas with short-range interactions, three-body losses are proportional to the probability that two particles will approach within a distance equal to the size of their bound state and that a third particle will venture within interaction range to take away excess kinetic energy. For dipoles, we can see that for inelastic scattering to occur, two dipoles must approach within each other’s centrifugal barrier, but due to long-range interactions, the third can absorb excess energy from a distance. Worse still, because the gas interaction energy is not extensive, the whole gas can effectively absorb excess energy from a collision pair simultaneously.

Referring back to Fig. 2 and comparing the solid and dashed lines, we see that the cutoff starts to affect $T_c$ only around $\lambda \lesssim 5$. At these densities, the average distance between dipoles is only 2 to 30 times larger than the size of the shallowest dimers (see the discussion in Fig. 1). This is much smaller than is normal for typical dilute gases with short-range interactions. Given that, once the molecules have tunneled, they can dimerize by expelling energy to multiple external dipoles at once and given their proximity to these other dipoles, it is not unreasonable to expect dimerization to occur at very high probability inside the centrifugal barrier (this also agrees with exact numerical calculations that give a three-body recombination rate of dipolar fermions proportional to $C_{dd}^{\lambda=3}$ [33]). If we combine this with the possibility of long-lived scattering chain complexes [31] and of inelastic spin-flip interactions in atoms [20], then to us it seems reasonable that our effective potential should be valid also for chemically stable molecules and dipolar atoms as well (for dipolar atoms, the bound states in Fig. 1 just represent the shallowest rovibrational states of a molecule).

VI. DISCUSSION

A. Comparison with other work

It is worthwhile to now compare our results to those of Ref. [1] to understand where and how they differ. In Ref. [1], the same calculation was performed, except using the renormalization method from Refs. [56,57]. That is, instead of finding nonsolution to the gap equation,

$$\Delta(k) = -\int \frac{d^3q}{(2\pi)^3} V(k,q) \frac{\Delta(q)}{2E(q)} \tanh \left( \frac{E(q)}{2T} \right), \quad (14)$$

one solves the renormalized gap equation,

$$\Delta(k) = \int \frac{d^3q}{(2\pi)^3} T(k,q) \left\{ \frac{1}{2\delta(k)} - \frac{\tanh \left( \frac{E(q)}{2T} \right)}{2E(q)} \right\} \Delta(q), \quad (15)$$

which is the same equation but in terms of the scattering $T$ matrix $T$, rather than the potential $V$. In order to solve this equation the authors first make the approximation $T = V$ (the Born approximation) and then to first order (small $k$) remove the $\frac{1}{2\delta(k)}$ term. They are therefore solving almost the same equations as we do, but with a $V$ that is not cut off at $r_b$.

However, they use the approximation that $\Delta$ is concentrated around the Fermi surface, therefore making the region around $k_F \sim r_b^{-1}$ irrelevant for small densities or small interaction strengths (i.e., large $\lambda$). It is therefore not surprising that in Fig. 2 both solutions agree closely at large values of $\lambda$.

As $\lambda \to 1$, however, the cutoff becomes very relevant, and the two solutions diverge. Although we have justified our methodology in detail here, one might be tempted to argue that the method presented in Ref. [1] has a physical basis in the fact that it does not depend on any cutoff, whereas our solutions are highly dependent on the choice of $r_b$ for high densities. Below we elucidate how the renormalization method presented in Ref. [1] does implicitly introduce a short-range cutoff.

Such an assertion is based on the idea that the term in brackets in Eq. (15) approaches zero for large $k$, which makes the details of $T$ irrelevant at large $k$ and therefore “renormalizes” out the short-range behavior the gas. However, for the case of a dipolar potential considered here, things are more complicated. First, notice that due to its $r^{-3}$ behavior, a bare dipolar potential does not form a well-defined Hamiltonian. That is, if we use a cutoff, as that cutoff approaches zero, the number of negative energy eigenstates approaches infinity, and the energy of the deepest eigenstates approaches negative infinity. The $T$ matrix for a bare dipolar interaction is therefore also not defined without also choosing a cutoff.

For identical fermions, however, this difficulty is somewhat allayed by the presence of the centrifugal barrier. Because identical fermions with low scattering energy cannot approach closely, $T$, for long wavelengths, is mostly independent of the cutoff. This is referred to as quasuni verses dipolar scattering [59]. Also, we can easily calculate this universal small $k$ behavior of $T$ by noting that, because of this insensitivity, we can put the cutoff anywhere within the centrifugal barrier and still get the same answer (provided the cutoff does not put the system on resonance). If we choose the cutoff to be at $r_b$ and choose $V$ to be zero everywhere within that cutoff, it is easy to see that $V$ is small everywhere, and we can therefore use the Born approximation $T \approx V$. This is exactly what is done in Ref. [1]. It is important to realize that in choosing the Born approximation in this way, a cutoff is implicitly chosen. For example, as we move farther inside the centrifugal barrier of a dipolar potential, the strength of the potential is much stronger, and because of this, to correctly describe $T$ in this case, one would have to use the second-order Born approximation. Such a choice for $T$ would be equivalent to using a different implicit value for the cutoff.

For large values of $\lambda$ our solutions are insensitive to the choice of $r_b$ just as the solutions of Ref. [1] are insensitive to the approximation used to calculate $T$. As $\lambda$ gets smaller, both our results and those of Ref. [1] become highly dependent on this choice.

At this point we should note that, although the method used in Ref. [1] is equivalent to choosing a cutoff, it is not equivalent to making the potential zero inside this cutoff. More specifically, they are effectively choosing an effective potential
$V'$ such that the $T$ matrix generated by $V'$ is equal to the bare dipolar potential. This $V'$ agrees with our $V_{dd}^{\text{eff}}$. Eq. (2), outside $r_b$ but not inside. There is no reason \textit{a priori} why either choice for the effective potential would be more correct. In this work we have argued that it is unreasonable to expect the region inside the centrifugal barrier to contribute to the superfluid, and the optimal choice is zero.

**B. The $k_F \sim 1/r_b$ regime**

In order for a superfluid to appear, the thermalization rate into bound Cooper pairs must be faster than the rate of quenching into tightly bound pairs and trap loss. Although most of this work is dedicated to dealing with the effect of this quenching, we have not explicitly calculated any transition rates. Rather, we have noted that, within certain temperature-density regimes, a transition to a BCS state cannot occur faster than the quenching rate because the BCS state itself is the unstable tightly bound pairs. We have therefore calculated a temperature upper bound for which a BCS is possible provided thermalization could occur fast enough.

The $k_F \sim 1/r_b$ region is of interest because it is the quantum degenerate regime where the kinetic energy and dipolar energy are of comparable order. The results here show that a homogeneous dipolar gas should be unstable in this regime, and hence $T_c$ goes to zero in Fig. 2. However, a number of experimental methods exist which could be used to artificially stabilize the gas. In particular, the method presented in Refs. [9,10] or the bilayer trap discussed in Ref. [12] could both be used to overcome the problems discussed here.

**C. Resonant scattering**

All of the results discussed here assume that the dipolar potential is off resonance. In the case of resonant scattering, experiments have already shown that the transition temperature can be made as high as $0.2T_F$. This is much higher than the results given here for BCS superfluidity due to the long-range part of the potential. It is clear then that for the case of resonant scattering, any contribution from the long-range part will be overwhelmed by the resonant scattering, and the system should behave like a system of short-range, $p$-wave-interacting atoms. As discussed in Sec. II, these systems have already been shown to be unstable, and there is no reason to believe a dipolar gas would be any different given the insignificance of the long-range contribution in the resonant regime.

**D. Conclusion**

The first purpose of this work was to show that previous work on dipolar Fermi gases has calculated a transition to a tightly bound BEC pair and not a BCS superfluid. We pointed out the inherit instability of these pairs and investigated the effect this phenomenon has on the transition temperature. The second purpose of this work was to present a general numerical method for calculating $T_c$ for systems where the particles have complicated self-energy configurations. It is particularly well suited to the dipolar gas problem because of the anisotropy of the Fermi surface, and it is also applicable more generally to systems with complicated self-energies.

**APPENDIX A: ANALYTIC AND NUMERICAL TECHNIQUES**

1. **The $K$-matrix integral**

The $K$ matrix [Eqs. (12) and (13)] typically has a few hundred elements corresponding to each different basis point. For each basis point, the integral in Eqs. (12) and (13) must be performed. Furthermore, every time $\phi$ or $\tau$ is changed, every basis point must be recalculated. For the case of an isotropic $V(k)$, the integral is not overly difficult because the angular part disappears. For the anisotropic case, however, each grid point requires that a three-dimensional integral be performed (although in the case of dipoles, cylindrical symmetry removes one of the angular dimensions, leaving a two-dimensional integral). Also, the fact that the potential is anisotropic means that the cross terms of different $l$ and $l'$ become nonzero, leading to still more bases to calculate. All this is compounded by the fact that the integrand is very tightly peaked near the Fermi surface, especially at low temperatures. For these reasons, the integral is too challenging to be done by brute-force numerical methods. Fortunately, analytic solutions exist for the radial part of the integral, which is the most time-consuming because it contains the peak at the Fermi surface.

To calculate $K(i,\hat{k}) = \int_{-\infty}^{\infty} \frac{dk}{k^2} \tanh \frac{\beta k}{2} \delta(k-E_{q})$, we can expand $\Sigma(k,k)$ in a power series to order $k^2$. This gives $\kappa = \alpha(k)^2 + \beta(k)k + \omega(k)$. We then get the following asymptotic formula for the indefinite integral:

$$\int dk \frac{k^2}{2(\alpha k^2 + \beta k + \omega)} \tanh \left( \frac{\alpha k^2 + \beta k + \omega}{2T} \right) \sim \frac{\sqrt{2T}}{4\alpha^{3/2}} A - \frac{\beta^2}{16\alpha^{5/2}\sqrt{2T} C},$$

where

$$A = \tanh \left( \frac{\nu_F^2 - \nu_F^2}{4T} \right) \left\{ \nu_F + \frac{\nu_F}{2} \ln \left( \frac{\nu_F - \nu}{\nu_F + \nu} \right) \right\}$$

$$- \left( \frac{\nu_T^2}{4} \right) + \theta \left( \nu_T^2 - \nu_F^2 \right) \sqrt{\frac{\nu_F}{\nu_T}} \left\{ -2 + \nu + \ln \left( \frac{4 \nu_F^4}{\pi T} \right) \right\}$$

$$+ \left( \frac{\nu_T^2}{12 \nu_F^2} \right) + 7 \left( \frac{\nu_T^2}{T} \right)^4 + O \left( \frac{T^6}{\nu_F^4} \right),$$

$$B = \tanh \left( \frac{\nu_F^2 - \nu_F^2}{4T} \right) \left\{ \nu_T^2 - \nu_F^2 \right\} \left\{ \nu_F + \nu_F \right\} - i \frac{\pi}{2}$$

$$+ \theta \left( \nu_T^2 - \nu_F^2 \right) 2 \left\{ \nu_T^2 - \nu_F^2 \right\} \left\{ \nu_F + \nu_F \right\},$$

$$C = \tanh \left( \frac{\nu_F^2 - \nu_F^2}{4T} \right) \left\{ \nu_F + \nu_F \right\}$$

$$+ \theta \left( \nu_T^2 - \nu_F^2 \right) 4 \left\{ \nu_T^2 - \nu_F^2 \right\} \left\{ \nu_T^2 - \nu_F^2 \right\}$$

$$- \left( \frac{\nu_T^2}{4 \nu_F^2} \right) + \left( \frac{\nu_T^2}{96 \nu_F^4} \right) + O \left( \frac{T^6}{\nu_F^4} \right),$$

and we use the definitions $\nu = \sqrt{2ak + \beta}$, $\eta = \frac{\beta}{a} - \omega$, and $\nu_T = \pm \sqrt{2\eta}$. This formula is an asymptotic solution for the indefinite integral in the limit $|k(k)| \rightarrow \infty$. It is valid as long as $k$ is either strictly increasing or strictly decreasing in the integration region. It converges very quickly, and for
\( |\kappa(k)/2T| \geq 12 \) it is exact to ten decimal places. The correct solution for \( v_F \) depends on \( \kappa \) and \( \alpha \). If \( \kappa \) is strictly increasing and \( \alpha > 0 \) or if \( \kappa \) is strictly decreasing and \( \alpha < 0 \), then one must take the positive solution; otherwise, one needs the negative solution. If one requires more accuracy, the expansion must be carried out beyond \( O(T^0 / V)^{\frac{3}{2}} \). If an end point of one of the grid points lies too close to the Fermi surface, then either the grid point can be moved, or the radial integral can be done numerically for only that particular point.

This formula can be derived by changing the integration variable to \( k \) and using integration by parts to get a sech^2 in the integral instead of tanh. Because sech^2 decays exponentially quickly, we can change the integration limits from \([k(x_i), k(x_{i+1})]\) to \([−\infty, \infty]\) and perform the remaining integral using standard integrals.

With this analytic solution for the radial part of the integral, the angular part can be done numerically in a short amount of time.

2. The \( J = \int_1^\infty \frac{dr}{r^2} \int j_i(kr) j_i(k'r) \) integral

Expanding \( V(k) \) into its radial components leaves one with an integral of the form of \( J \) in Eq. (6). Depending on the form of the potential, there may be a different power of \( r \) in the integral. This integral needs to be calculated once for each element in the vector \( V \). It contains a number of elements on the order of the number of bases squared. In our case, to calculate the \( V \) matrix, the \( J \) integral had to be calculated over 40 000 times. For this reason, the integral must be calculated very quickly as well as accurately. The following method is sufficient for this task.

For \( k \approx k' \), the integral must be performed as follows. First, note that the Bessel functions converge slowly as \( r \to \infty \) and are oscillatory. This makes straight numerical integration very difficult. However, we should recall the asymptotic properties of the Bessel functions

\[
j_i(kr) \to j_i^\infty(kr) \quad \text{as} \quad r \to \infty, \quad (A5)
\]

where

\[
j_i^\infty(kr) = \frac{1}{kr} \cos \left[ kr - (l + 1) \frac{\pi}{2} \right]. \quad (A6)
\]

If we define

\[
J_{i,i}^\infty(k,q) = \int_1^\infty \frac{1}{r} j_i^\infty(kr) j_i^\infty(qr) dr, \quad (A7)
\]

then the integrand in \( \tilde{J} \) has the oscillatory asymptotic part removed, making numerical integration much easier, and \( J_{i,i}^\infty(k,q) \) can be calculated analytically using standard techniques. The full integral is then

\[
J_{i,i}(k,q) = \tilde{J}_{i,i}(k,q) + J_{i,i}^\infty(k,q). \quad (A9)
\]

The above technique only removes the oscillatory part of \( j \) to first order. When we have \( k \ll q \) or \( q \ll k \), the integrand becomes extremely oscillatory even with the \( j^\infty \) terms removed. The numerical integration becomes so time-consuming that calculating the integral even once is difficult, let alone thousands of times. Fortunately, we can expand \( J_{i,i}(k,q) \) in a power series expansion that is valid for \( k \ll q \) or \( q \ll k \). Here we will assume \( k \ll q \).

Let \( \rho_i^{(n)}(kr) \) be the \( n \)th order series expansion of \( j_i(kr) \) about \( k = 0 \). Then define the indefinite integral

\[
\mathcal{J}^{(n)}_{i,i}(k,q;r) = \int_1^\infty \frac{1}{r} \rho_i^{(n)}(kr) j_i(qr) dr, \quad (A10)
\]

\[
\mathcal{J}^{(n)}_{i,i}(k,q;r) \text{ is a divergent expansion of the function } \int_1^\infty \frac{1}{r} j_i(kr) j_i(qr) dr. \quad \text{For small } r \text{ the two functions agree},
\]

but no matter how many terms in the expansion of \( \rho_i^{(n)}(kr) \) one uses, the function \( \mathcal{J}^{(n)}_{i,i}(k,q;r) \) will always diverge for large \( r \), and therefore one has to be careful about attempting erroneous actions such as \( J_{i,i}(k,q) = \mathcal{J}^{(n)}_{i,i}(k,q;\infty) − \mathcal{J}^{(n)}_{i,i}(k,q;0) \).

However, note the following. The integrand \( \frac{1}{r} j_i(kr) j_i(qr) \) converges to zero as \( r \) increases. This means that the approximate integrand \( \frac{1}{r} \rho_i^{(n)}(kr) j_i(qr) \) also converges to zero before it blows up at larger values of \( r \). Let \( r_{\text{max}}^{(n)} \) be the value of \( r \) at which \( \frac{1}{r} \rho_i^{(n)}(kr) j_i(qr) \) is closest to zero and still a good approximation for \( \frac{1}{r} j_i(kr) j_i(qr) \). If \( \frac{1}{r} j_i(kr_{\text{max}}) j_i(qr_{\text{max}}) \) is sufficiently small, then

\[
J_{i,i}(k,q) \approx \int_1^{r_{\text{max}}^{(n)}} \frac{1}{r} j_i(kr) j_i(qr) dr
\]

\[
\approx \mathcal{J}^{(n)}_{i,i}(k,q;r_{\text{max}}) − \mathcal{J}^{(n)}_{i,i}(k,q;0)
\]

\[
\approx −\mathcal{J}^{(n)}_{i,i}(k,q;0). \quad (A11)
\]

Now it turns out that the smaller \( k \) is, the faster the integrand converges, and the fewer terms (smaller \( n \)) one needs to consider in \( \rho_i^{(n)}(kr) \). So it in fact turns out that \( −\mathcal{J}^{(n)}_{i,i}(k,q;0) \) is the series expansion of \( J_{i,i}(k,q) \) around small \( k \). We can likewise do the same for small \( q \).

Finally, it is important to note that \( J_{i,i}(k,q) \) is not analytic at \( k = q \). This means that the small \( k \) and small \( q \) expansions can only work up to a point. Once we are in the \( k \approx q \) regime, we must resort to the first method described above.
