The extraction of hadronic final states with a charm quark, $c$, denoted by the Belle detector at the KEKB asymmetric-energy $b$-hadron collider. The branching fractions of the decays are measured to be $B(B_s \rightarrow D_{s}^{+} X \ell^{+}\nu) = [8.2 \pm 0.2(\text{stat}) \pm 0.4(\text{syst}) \pm 0.2(\text{ext})]\%$ and $B(B_s \rightarrow D_{s}^{*-} X \ell^{+}\nu) = [5.4 \pm 0.4(\text{stat}) \pm 0.4(\text{syst}) \pm 0.9(\text{ext})]\%$, where the first two uncertainties are statistical and systematic and the last is due to external parameters. The measurement also provides an estimate of the $B_s^{(*)} \bar{B}_s^{(*)}$ production cross-section, $\sigma(e^+e^- \rightarrow B_s^{(*)}\bar{B}_s^{(*)}) = (53.8 \pm 1.4(\text{stat}) \pm 4.0(\text{syst}) \pm 3.4(\text{ext}))$ pb, at the center-of-mass energy $\sqrt{s} = 10.86$ GeV.

INTRODUCTION

Analyses of semileptonic decays $B \rightarrow X_c \ell \nu$, where $X_c$ denotes a hadronic final state with a charm quark, play an important role in the determination of the CKM matrix element $|V_{cb}|$. The extraction of $|V_{cb}|$ from the measured decay rates relies on form factors that describe the accompanying strong interaction processes. Measurements of semileptonic $B_s$ decays provide complementary information to test and validate the QCD calculations of these form factors. Since large $B_s$ samples have become available at Belle and the experiments at the Large Hadron Collider, the interest in the topic of semileptonic $B_s$ decays has intensified recently. Theoretical predic-
tions of form factors and branching fractions are based on QCD sum rules [1–4], lattice QCD [5, 6] and constituent quark models [7–15]. The predicted exclusive branching fractions vary from 1.0% to 3.2% for $B_s \rightarrow D_s \ell \nu$ decays and from 4.3% to 7.6% for $B_s \rightarrow D_s^* \ell \nu$ decays. There are also predictions for the modes with higher excitations of the $D_s$ meson, denoted hereinafter by “$D_s^{(*)}$”. The LHCb and DØ experiments have measured the semi-inclusive branching fractions of the decays $B_s \rightarrow D_{s1}(2536)\eta \mu^+ \nu$ and $B_s \rightarrow D_{s2}^*(2573)\eta \mu^+ \nu$, where the $D_s^{(*)}$ mesons were reconstructed in $D^{(*)}K$ final states [16, 17]. The inclusive semileptonic branching fraction of $B_s \rightarrow X \ell \nu$ decays was recently measured by Belle and BaBar [18, 19] and found to be in agreement with the expectations from SU(3) flavor symmetry [20, 21]. We report here the first measurements of the semi-inclusive branching fractions $B(B_s \rightarrow D_s X \ell \nu)$ and $B(B_s \rightarrow D_s^* X \ell \nu)$ using the Belle $\Upsilon(5S)$ dataset. The number of $B_s^{(*)} \bar{B}_s^{(*)}$ pairs in the dataset,

$$N_{B_s \bar{B}_s} = \sigma(e^+ e^- \rightarrow B_s^{(*)} \bar{B}_s^{(*)}) \cdot L_{T(5S)},$$  

(1)

where $\sigma(e^+ e^- \rightarrow B_s^{(*)} \bar{B}_s^{(*)})$ is the production cross-section and $L_{T(5S)}$ is the integrated luminosity, is the limiting systematic uncertainty in this measurement and other untagged $B_s$ measurements at Belle [22]. The value $N_{B_s \bar{B}_s} = (7.1 \pm 1.3) \times 10^6$ was obtained from a measurement of the inclusive $D_s$ yield in the dataset [23]. The measured $B_s \rightarrow D_s X \ell \nu$ yield, together with an estimate for the branching fraction $B(B_s \rightarrow D_s X \ell \nu)$, provides an alternative way to determine $N_{B_s \bar{B}_s}$. A similar approach was already pursued by the LEP experiments [24–26] and LHCb [27].

DETECTOR, DATA SAMPLE AND SIMULATION

The Belle detector located at the KEKB asymmetric-energy $e^+e^-$ collider [28] is a large-solid-angle magnetic spectrometer that consists of a silicon vertex detector, a 50-layer central drift chamber (CDC), an array of aerogel threshold Cherenkov counters (ACC), a barrel-like arrangement of time-of-flight scintillation counters (TOF), and an electromagnetic calorimeter (ECL) comprised of CsI(Tl) crystals located inside a superconducting solenoid coil that provides a 1.5 T magnetic field. An iron flux-return located outside of the coil is instrumented to detect $K^0_L$ mesons and to identify muons (KLM). The detector is described in detail elsewhere [29].

This analysis uses a dataset with an integrated luminosity of $L_{T(5S)} = (121.4 \pm 0.8) \text{ fb}^{-1}$ collected at a center-of-mass (CM) energy of $\sqrt{s} = 10.86 \text{ GeV}$ [30], corresponding to the mass of the $\Upsilon(5S)$ resonance. The $B_s$ mesons are produced in pairs in the following production modes, with the respective production fractions given in parentheses: $B_s^* \bar{B}_s^* ((87.8 \pm 1.5)\%), B_s^* \bar{B}_s ((6.7 \pm 1.2)\%)$ and $B_s \bar{B}_s ((2.6 \pm 2.6)\%)$ [31]. All production modes are considered for the analysis. Moreover, we use a 62.8 fb$^{-1}$ sample collected below the production threshold for open $B$ production to study the continuum processes $e^+ e^- \rightarrow q\bar{q}$ $(q = u, d, s, c)$.

A sample of simulated events with a size corresponding to six times the integrated data luminosity is generated using Monte Carlo (MC) techniques. The simulated data emulate the different types of events produced at the $\Upsilon(5S)$ CM energy, comprising events with $B$ and $B_s$ decays, bottomonium production and the $q\bar{q}$ continuum processes. The events are generated with the EvtGen package [32] and are processed through a GEANT [33] based detector simulation. Final state photon radiation is added with the PHOTOS package [34].

The branching fractions in the simulation are set to the latest averages from the Particle Data Group [31]. However, for semileptonic $B_s$ decays only measurements of the $D_{s1}(2536)$ and $D_{s2}^*(2573)$ modes are available, so we use instead the calculations from Faustov and Galkin [8], who predict the full set of branching fractions and thus provide a self-consistent picture of the semileptonic width. The $B_s$ semileptonic decay modes considered in this analysis, with their corresponding branching fractions given in parentheses, are: $D_s (2.1\%)$, $D_s^* (5.3\%)$, $D_{s1}(2536) (0.84\%)$, $D_{s0}^*(2317) (0.36\%)$, $D_{s1}(2460) (0.19\%)$ and $D_{s2}^*(2573) (0.67\%)$. The decays $B_s^0 \rightarrow D_s^{(*)} \ell \nu$ are described by the Caprini-Lellouch-Neubert model [35], based on heavy quark effective theory [36]. Assuming SU(3) flavor symmetry, the form factors of the semileptonic $B_s$ decays are taken to be identical to the ones measured in the corresponding $B$ decays [37]; we use the following values of the form factor parameters: $\rho_D = 1.186$ for $B_s \rightarrow D_s \ell \nu$ decays, and $\rho = 1.207, R_1 = 1.403, R_2 = 0.854$ for $B_s \rightarrow D_s^* \ell \nu$ decays. The $B_s^0 \rightarrow D_s^{(*)} \ell \nu$ decays are described by the Leibovich-Ligeti-Stewart-Wise (LLSW) model [38] originally developed for $B \rightarrow D^{(*)} \ell \nu$ decays. We replace in this model the $B$ and $D^{(*)}$ masses by the $B_s$ and $D_s^{(*)}$ masses, respectively. The nominal branching fractions for the $D_s^{(*)}$ decays in this analysis are listed in Table I.

| TABLE I: Nominal branching fractions of $D_s^{(*)}$ decays to different final states in the MC simulation. The branching fraction of the $D_s^* \rightarrow D_s X$ decays is set to 100% and this crossfeed is included in the calculation of the branching fractions to the $D_s X$ final state. |

ANALYSIS OVERVIEW

This analysis is based on samples of reconstructed $D_s^+\ell^+$ and $D_s^-\ell^-$ pairs [39]. Incorrectly reconstructed $D_s$ and $D_s^*$ candidates constitute a large background in the analysis. We therefore perform fits to the $D_s^{(*)}$ mass distributions to determine the yields of events with correctly reconstructed $D_s^{(*)}$ mesons. These events contain the following signal and background categories:

1. $e^+e^- \rightarrow \bar{c}\bar{c}$ continuum;
2. $B \rightarrow D_s^{(*)}K\ell\nu$ decays, which have a branching fraction of $(6.1 \pm 1.0) \times 10^{-4}$ [31, 40, 41];
3. opposite-$B(s)$ background, where a lepton candidate is combined with a $D_s^{(*)}$ meson from the second $B_s$ in the event; the lepton candidate can be either a primary lepton from a $B(s) \rightarrow X\ell\nu$ decay, a lepton originating from a secondary decay or a misidentified hadron track;
4. same-$B(s)$ background from secondary leptons and from hadron tracks misidentified as leptons, which stem from the decay of the same $B_s$ meson as the reconstructed $D_s^{(*)}$ meson;
5. signal: in the $D_sX\ell\nu$ channel, the signal comprises $B_s \rightarrow D_s\ell\nu$ decays and crossfeed from $B_s \rightarrow D_s^*\ell\nu$ and $B_s \rightarrow D_s\ell\nu$ decays; in the $D_s^*X\ell\nu$ channel, the dominant signal contributions are $B_s \rightarrow D_s^*\ell\nu$ decays with a small crossfeed contribution from $B_s \rightarrow D_s\ell\nu$ decays.

The continuum background is estimated using off-resonance data, and the $B \rightarrow D_s^{(*)}K\ell\nu$ background is estimated from MC simulation. We use the kinematic properties of the reconstructed decay to determine the normalisations of the other three components from data. For this, we consider the lepton momentum in the CM system of the $e^+e^-$ collision, $p_\ell^*$, and the variable

$$X_{\text{mis}} = \frac{E^*_{B_s} - (E^*_{D_s,\ell} + p^*_{D_s,\ell})}{p^*_{B_s}},$$

where $E^*_{B_s}$ is the energy of the $B_s$ meson in the CM system approximated by $\sqrt{s}/2$; $p^*_{B_s}$ is the momentum of the $B_s$ meson in the CM system approximated by $\sqrt{s}/4 - m^2_{B_s}$; $E^*_{D_s,\ell} = E^*_\ell + E^*_{D_s}$ is the sum of the reconstructed energies in the CM system and $p^*_{D_s,\ell} = |p^*_\ell + p^*_{D_s}|$ is the absolute value of the sum of the reconstructed lepton and $D_s$ momenta in the CM system. When the $D_s$ meson and the lepton candidate stem from the decay of the same $B_s$ meson, $X_{\text{mis}}$ takes values larger than $-1$ because the momentum of the uncorrected $B_s$ meson products, $p^*_{\text{other}}$, is constrained by the triangle inequality $p^*_{B_s} - p^*_{D_s,\ell} \leq p^*_{\text{other}}$ and by $p^*_{\text{other}} \leq E^*_{\text{other}} = E^*_{B_s} - E^*_{D_s,\ell}$.

We divide the data samples into three regions:

A: $X_{\text{mis}} < -1$,
B: $X_{\text{mis}} \geq -1$ and $p^*_\ell < 1.4$ GeV,
C: $X_{\text{mis}} \geq -1$ and $p^*_\ell \geq 1.4$ GeV.

As these regions are later used to determine the signal yields, we refer to them as “counting regions” in the following. Region A contains only opposite-$B(s)$ background and can be used to determine the normalisation of this background. The normalisation of the other two components can be extracted from the measured yields in regions B and C, which have an enhanced fraction of same-$B(s)$ background and signal events, respectively. The boundary $p^*_\ell = 1.4$ GeV is chosen to achieve approximately equal event yields in regions B and C. The analysis is insensitive to the modeling of the $X_{\text{mis}}$ distribution for signal decays, which depends on the mass of the $B_s^*$ meson, $m_{B_s^*}$, and is thus strongly influenced by the poor precision on $m_{B_s^*}$. The semi-inclusive branching fractions are obtained from the relation

$$B(B_s \rightarrow D_s^{(*)}X\ell\nu) = \frac{N_{\text{sig}}}{2 \cdot N_{B,B_s}\epsilon B_{D_s^{(*)}}},$$

where $N_{\text{sig}}$ is the measured signal yield, $\epsilon$ is the average signal efficiency and $B_{D_s^{(*)}}$ is the branching fraction of the reconstructed $D_s^{(*)}$ decay mode:

$$B_{D_s} = B(D_s^- \rightarrow \phi\pi^-; \phi \rightarrow K^+K^-),$$
$$B_{D_s^*} = B(D_s^{*-} \rightarrow D_s^-\gamma) \cdot B_{D_s}.$$

EVENT SELECTION

We select tracks originating from the interaction region by requiring $|dz| < 2.0$ cm and $dr < 0.5$ cm, where $dz$ and $dr$ are the impact parameters along the $e^+e^-$ beam and in the transverse plane, respectively. Kaon or pion hypotheses are assigned to the tracks based on a likelihood combining the information from the Cherenkov light yield in the ACC, the time-of-flight information of the TOF and the specific ionization $dE/dx$ in the CDC. The kaon (pion) identification efficiency for tracks with a typical momentum of 0.75 GeV is about 96% (92%), while the rate of pions (kaons) being misidentified as kaons (pions) is 7% (2%). The kaon and pion candidates are used to reconstruct $D_s$ mesons in the high-purity decay channel $D_s^- \rightarrow \phi\pi^-; \phi \rightarrow K^+K^-$. A $D_s$ candidate is retained in the analysis if it has a reconstructed mass, $M_{KK\pi}$, within a ±65 MeV window around the nominal $D_s$ mass, $m_{D_s} = 1968.5$ MeV [31], that includes large enough sidebands to determine the combinatorial background of random $KK\pi$ combinations. The reconstructed di-kaon invariant mass, $M_{KK}$, is required to be in the mass window between 1004 and 1034 MeV, corresponding to three
times the FWHM of the reconstructed $\phi$ mass peak. To suppress combinatorial background, we impose the criterion $|\cos\theta_{\text{hel}}| > 0.3$ on the helicity angle, defined as the angle between the momentum of the $D_s$ and the $K^-$ in the rest frame of the $\phi$ resonance.

The $D_s$ candidates with a reconstructed mass, $M_{KK\pi}$, within the range between 1953.5 and 1983.5 MeV, corresponding to three times the RMS of the $D_s$ mass peak, are utilized for the reconstruction of $D^*_s$ candidates in the dominant decay channel $D^*_s \rightarrow D_s\gamma$. Photon candidates are reconstructed from ECL clusters that are not attributed to a track candidate. The photon candidate must have a minimum energy of 125 MeV in the lab frame and the ratio of the energy deposit in the central 3 $\times$ 3 cells of the ECL cluster to the energy deposit in the central 5 $\times$ 5 cells must be at least 90%. To veto photons from $\pi^0$ decays, we combine the photon candidate with any other photon candidate in the detector and require that the invariant mass of the two photons differs from the nominal $\pi^0$ mass [3] by more than 5 MeV, corresponding to about 0.8 times the experimental resolution. The angle between the $D_s$ meson and the photon in the lab frame is typically less than 90$^\circ$, so only candidates fulfilling this requirement are retained. The $D^*_s$ candidates whose mass difference between the reconstructed $D^*_s$ and $D_s$ candidates, $\Delta M = M_{KK\pi\gamma} - M_{KK\pi}$, lies between 78.8 and 208.8 MeV are retained.

Electron and muon candidates are reconstructed from tracks that are not used for the $D^*_s$ reconstruction. Electrons are selected based on the position matching between the track and the ECL cluster, the ratio of the energy measured in the ECL to the charged track momentum, the transverse ECL shower shape, specific ionization in the CDC and the ACC light yield. Muons are identified using their penetration depth and the transverse scattering in the KLM. Hadron tracks misidentified as leptons and leptons from secondary decays tend to have lower momenta than primary leptons and are suppressed by rejecting lepton candidates with a momentum, the transverse ECL shower shape, specific ionization, the angle between the track and the ECL cluster, the ratio of the energy deposit in the central 5 $\times$ 3 cells of the ECL cluster to the energy deposit in the central 5 $\times$ 5 cells must have a minimum energy of 125 MeV in the lab frame attributed to a track candidate. The photon candidate $D^*_s$ candidates with an oppositely charged lepton candidate $\ell^-$. To suppress background from $c\bar{c}$ continuum, we reject events where the normalised $D_s$ momentum, $x(D_s) = p^*(D_s)/\sqrt{s/4 - m^2_{D_s}}$, is larger than 0.5 (for explanations, see Ref. [18]). Further suppression of the $c\bar{c}$ continuum background is achieved by rejecting events with a jet-like topology characterised by $|\cos\theta_{\text{thrust}}| > 0.8$, where $\theta_{\text{thrust}}$ is the thrust angle defined by the two thrust axes maximizing the projection of the momenta of the tracks and photon candidates of the $B_S^0$ candidate and the rest of the event, respectively.

After applying the selection criteria, 7.9% (0.4%) of the events contain more than one (two) $D^*_s \ell^-$ candidate(s). We perform a $\chi^2$ fit to the vertex of the three tracks used for $D_s$ reconstruction and select the candidate with the best goodness-of-fit. This approach selects a correct candidate in 80% of the cases. The selected $D_s$ candidate in an event is used for $D^*_s$ reconstruction; in 36.2% (9.7%) of the events, more than one (two) $D_s\gamma$ combinations meet the $D^*_s$ requirements. We choose the photon candidate with the highest energy fraction deposited in the central 3 $\times$ 3 cells of a 5 $\times$ 5 cell ECL cluster. In the case that more than one photon candidate deposits all of its energy in the central 3 $\times$ 3 cells of the cluster, the candidate with the higher energy in the lab frame is selected. If two or more lepton candidates pass all of these selection criteria (2.1% of all events), we choose a random lepton candidate.

**FIT RESULTS**

**$D_s$ fits**

We determine the yields of correctly reconstructed $D_s$ mesons with binned extended maximum likelihood fits to the reconstructed $D_s$ mass, $M = M_{KK\pi}$, in 50 equal bins, indexed by $j$. The probability density function (PDF) of correctly reconstructed $D_s$ mesons, $P_{\text{sig}}(M)$, is modeled by the sum of two Gaussian functions with a common mean. The PDF of the combinatorial background, $P_{\text{bkg}}(M)$, is a first-order Chebychev polynomial. We do not determine the shape parameters from simulation, but rather allow them to vary as free parameters in the fit. The $D_s$ mass fits are performed simultaneously in the three counting regions ($i = A, B, C$) defined above. The width of the first Gaussian function, $\sigma_1$, the ratio of the widths of the two Gaussian functions, $r_\sigma$, and the ratio of the normalisations of the two Gaussian functions, $r_N$, are common fit parameters in all three regions. The means of the Gaussian functions, $\mu_i$, and the slopes of the polynomials describing the background, $b_i$, are fitted in each counting region individually. The likelihood function is:

$$L(\nu^{\text{sig}}, \nu^{\text{bkg}}, \theta) = \prod_{i=A,B,C} \prod_{\text{bins } j} \frac{\nu_{i1}^{n_i}}{n_i!} e^{-\nu_{i1}} \prod_{\text{jets } j} \frac{\nu_{ij}^{n_{ij}}}{n_{ij}!} e^{-\nu_{ij}}, \quad (6)$$
where $\nu^{\text{sig}} = (\nu_{A}^{\text{sig}}, \nu_{B}^{\text{sig}}, \nu_{C}^{\text{sig}})$ and $\nu^{\text{bkg}} = (\nu_{A}^{\text{bkg}}, \nu_{B}^{\text{bkg}}, \nu_{C}^{\text{bkg}})$ is the vector of signal and background yields in the three counting regions, $\theta = (\sigma_{i}, r_{\sigma}, r_{N}, \mu_{A}, \mu_{B}, \mu_{C}, b_{A}, b_{B}, b_{C})$ are the function parameters for the signal and background PDFs, and $n_{ij}$ and $\nu_{ij}$ are the observed and expected event yields in bin $j$ of counting region $i$, respectively, with $n_{i} = \sum_{j} n_{ij}$ and $\nu_{i} = \sum_{j} \nu_{ij}$. The expected event yield, $\nu_{ij}$, is a function of $\nu_{i}^{\text{sig}}, \nu_{i}^{\text{bkg}}$ and $\theta$:

$$\nu_{ij} = \int_{M_{j,\text{min}}}^{M_{j,\text{max}}} \left[ \nu_{i}^{\text{sig}} \mathcal{P}_{\text{sig}}(M) + \nu_{i}^{\text{bkg}} \mathcal{P}_{\text{bkg}}(M) \right] \, dM \, .$$

Figures 1 (a) and (b) show the $KK\pi$ mass distributions together with the fit results.

**$D_{s}^{*}$ fits**

The $D_{s}^{*}$ yields are determined from binned extended maximum likelihood fits to the mass difference $\Delta M$ in 25 equal bins, indexed by $j$. The combinatorial background is modeled by a third-order Chebyshev polynomial, $\mathcal{P}_{\text{bkg}}(\Delta M)$, whose parameters are constrained to the values obtained from fits to simulated background distributions. Since the background shapes vary for the different counting regions, the shape parameters are determined for each counting region separately. The signal peak is modeled by the sum of a Gaussian function and a Crystal Ball function [42] to account for energy loss due to material in front of the calorimeter:

$$\mathcal{P}_{\text{sig}}(\Delta M) \propto r_{N} \exp \left( -\frac{(\Delta M - \mu)^{2}}{\sigma^{2}} \right) + \left\{ \begin{array}{ll} \exp \left( -\frac{(\Delta M - \mu)^{2}}{2\sigma^{2}} \right) & \text{if } \frac{\Delta M - \mu}{\sigma} > -\alpha \\ \frac{1}{2\alpha} \left( \frac{\Delta M - \mu}{\sigma} \right)^{\alpha} & \text{if } \frac{\Delta M - \mu}{\sigma} \leq -\alpha \end{array} \right. \ .$$

A common mean, $\mu$, is used for both the Gaussian and the Crystal Ball functions. We perform a fit to the simulated signal distribution and fix the parameters $r_{N}$, $r_{\sigma}$, $\alpha$ and $\nu$ at the obtained values. The width $\sigma$ and the mean of the signal peak $\mu$ are varied in the fit to data; the parameter $\sigma$ is fitted simultaneously in all counting regions while $\mu$ is fitted individually for each counting region. The likelihood function is constructed analogous to Eqs. (6) and (7) with additional factors, to implement the constraints of the background PDF parameters taking into account their correlations. The results of the $\Delta M$ fits in the different counting regions are presented in Figs. 1 (c) and (d).

**Background subtraction**

To estimate the $c\bar{c}$ continuum background, the $D_{s}$ and $D_{s}^{*}$ yields are measured in $D_{s}^{*} \ell^{+}$ and $D_{s}^{*} \ell^{+}$ samples reconstructed in the off-resonance data. Since the size of the off-resonance data sample is not sufficient to determine the shape parameters in the fits, they are fixed to the values obtained in the fits to $\Upsilon(5S)$ data in the corresponding counting region. The CM energy, $\sqrt{s}$, in the expression for the $X_{\text{mis}}$ variable in Eq. (2) is replaced by a constant value of 10.876 GeV because, otherwise, the denominator would not be defined. The $c\bar{c}$ continuum yields from the fits to off-resonance data are multiplied by the scale factor $S = (L_{\Upsilon(5S)}/s_{\Upsilon(5S)})/(L_{\text{off}}/s_{\text{off}}) = 1.81 \pm 0.02$ to account for the differences in integrated luminosities, $L$, and the $1/s$ dependence of the $e^{+}e^{-} \rightarrow c\bar{c}$ cross section. Additionally, a shape correction for differences of the yields in the counting regions between off-resonance and $\Upsilon(5S)$ data is determined from MC simulation and applied. The small background from $B \rightarrow D(s)^{\pm}K\ell\nu$ decays is estimated from MC simulation using a simple phase space model. The backgrounds from continuum processes and $B \rightarrow D(s)^{\pm}K\ell\nu$ decays are subtracted in each counting region from the yields measured in $\Upsilon(5S)$ data.

**Signal extraction**

After subtraction of the continuum and the $B \rightarrow D(s)^{\pm}K\ell\nu$ background components, the remaining yields contain three contributions: opposite-$B(s)$ background, same-$B(s)$ backgrounds and signal. The three contributions are constrained by the event yields in the three counting regions. We introduce a scale factor, $a_{j}$, for each contribution, $j$. The determination of the scale factors is equivalent to solving a system of three linear equations with three unknowns. In order to obtain the uncertainties on the scale factors, we minimize:

$$\chi^{2} = \sum_{i=A,B,C} \frac{(D_{i} - \sum_{j} a_{j} N_{i,j})^{2}}{(\Delta D_{i})^{2} + \sum_{j}(a_{j}\Delta N_{i,j})^{2}} \ ,$$

where the index $i$ runs over the three counting regions, $D_{i}$ is the event yield determined by the fits to the $M_{KK\pi}$ or $\Delta M$ distributions in data, and $\Delta D_{i}$ is the statistical uncertainty of these fits, $N_{i,j}$ is the MC prediction for the contribution $j$, and $\Delta N_{i,j}$ is its statistical uncertainty. Table II lists the scale factors, $a_{j}$, obtained from the $\chi^{2}$ minimization and the signal yields,

$$N_{\text{sig}} = a_{\text{sig}} \cdot \sum_{i} N_{i,\text{sig}} \ .$$

Figure 2 shows the $X_{\text{mis}}$ and $p^{+}(\ell)$ distributions in the three counting regions after applying the scale factors $a_{j}$. 
FIG. 1: The $M_{KK\pi}$ distributions for $D_s^-\ell^+$ events and $\Delta M$ distributions for $D_s^*^-\ell^+$ events reconstructed in the $\Upsilon(5S)$ data for the three counting regions. The black points with uncertainty bars are the data, the red solid curve represents the total fit result, and the green dashed line is the fitted background component.
TABLE II: The scale factors, $a_j$, for the MC components obtained by minimizing the $\chi^2$ function defined in Eq. (8). The errors are the statistical uncertainties of the data and the MC sample. The signal yields are determined from Eq. (9). The signal efficiencies are obtained by averaging over the efficiencies for the $D_s^0 \ell \nu$, $D_s^+ \ell \nu$ and $D_s^{*-} \ell \nu$ modes, taking into account the expected relative abundance of the signal components. The given errors of the efficiencies are the statistical uncertainties of the MC sample.

**SYSTEMATIC UNCERTAINTIES**

The different sources of systematic uncertainties on the measured signal yields are described below. They comprise detector effects and the modeling of the signal and backgrounds. An overview can be found in Table V.

**Detector effects**

The uncertainty on the track finding efficiency is 0.35% per track and thus 1.4% for four tracks. The photon efficiency is studied with radiative Bhabha events, from which the uncertainty is estimated to be 2%. The calibration of kaon and pion identification efficiencies is estimated from a sample of reconstructed $D^{*+} \to D^{0}\pi^+$; $D^{0} \to K^{-}\pi^+$ decays. A variation of the obtained calibration factors within their uncertainties changes the measured signal yield by 1.4%. The efficiency of the lepton identification is estimated using the two processes $\gamma\gamma \to \ell^+\ell^-$ and $J/\psi \to \ell^+\ell^-$. The corresponding uncertainties on the measured signal yields are 1.0% and 1.6% for the electron and muon modes, respectively. The rates of hadrons being misidentified as leptons are estimated with the aforementioned $D^{*+}$ sample. The uncertainties due to this estimation are 0.1% ($D_s X\mu\nu$), 1.3% ($D_s X\mu\nu$), 0.1% ($D_s^* X\mu\nu$) and 1.9% ($D_s^* X\mu\nu$).

**Signal and background modeling**

To study uncertainties of the PDFs in the $D_s$ and $D_s^*$ fits, we repeat the fits with alternative fit models and assign the resulting change of the signal yield as systematic uncertainty. Herein, we focus on the tails of the signal peaks because they can be easily assigned in the fit to the background component without deteriorating the agreement of the data with the fitted curve. The signal PDF in the $D_s$ fits is modified by replacing the second Gaussian function by a bifurcated Gaussian function. This choice is motivated by a small asymmetry of the signal peak due to final state radiation. The normalization and the widths of the bifurcated Gaussian function are determined relative to the normalization and width of the Gaussian function from a fit to signal MC. These parameters are fixed in the fit to data. Based on the observed change of the signal yield, we assign a 3% PDF uncertainty. In the $D_s^*$ fits, the tails of the signal peak are

described by the Gaussian component of the signal PDF. When this Gaussian function is removed from the signal PDF, i.e. a Crystal Ball function only is used (cf. Ref. [43]), the signal yields decrease by 5%. Hence, we estimate the PDF uncertainty with 5%.

The uncertainty due to the continuum scale factor, $S$, is negligible. The uncertainty due to the shape correction for the continuum background is estimated as the full difference of the result with and without the correction applied, which is 1.2% and 0.3% for electrons and muons, respectively. To estimate the influence of the choice of the $B \rightarrow D_s^{(*)} K \ell \nu$ decay model, we replace the phase space model used in the nominal result with the ISGW2 model [44], assuming that the decay proceeds via $B \rightarrow D_s^0 \ell \nu$, $D_s^0 \rightarrow D_s^{(*)} K$. The use of this alternative model increases the signal yields by 0.3% and 0.1% for the $D_s X \ell \nu$ and $D_s^* X \ell \nu$ channels, respectively. We also vary the $B \rightarrow D_s^{(*)} K \ell \nu$ branching fraction by the measured uncertainty and observe no significant change in the measured yield. We test the stability of the signal extraction when the boundary between counting region B and C is varied between $p_T^\ell = 1.3$ and 1.5 GeV. The resulting change of the signal yields is consistent with the expected change due to the increase/decrease of statistics in the respective counting regions and, therefore, no systematic uncertainty is assigned.

The systematic uncertainty on the signal composition in the $D_s X \ell \nu$ channels is obtained by evaluating the effect of scaling the relative amount of $B_s \rightarrow D_s^{(*)} \ell \nu$ decays up and down by 30% and adjusting the $B_s \rightarrow D_s^{(*)} \ell \nu$ component such that the total number of MC events is conserved. This variation covers most of the recent theoretical predictions and causes a 4.7% change of the signal yields. To estimate the impact of scaling the relative amount of $B_s \rightarrow D_s^{(*)} \ell \nu$ decays, we double the $B_s \rightarrow D_s^{(*)} \ell \nu$ contribution in the signal component, which increases the signal yield by 1%. The $D_s^* X \ell \nu$ signal component is expected to be dominated by $B_s \rightarrow D_s^{(*)} \ell \nu$ decays and hence the uncertainty due to the amount of $D_s^{(*)} \rightarrow D_s^* X \ell \nu$ decays is negligible for this channel.

The $B \rightarrow D^{(*)} \ell \nu$ form factor parameters from Ref. [37] used to simulate the $B_s \rightarrow D_s^{(*)} \ell \nu$ decays are measured with an accuracy of 2-3%. However, SU(3) flavor symmetry breaking effects may cause deviations at the order of 10% [4]. To account for these differences, we vary each form factor parameter of a given decay independently up and down by 10%. The resulting average deviation from the nominal signal yield is added linearly for each variation. The uncertainty of the LLSW model for $B_s \rightarrow D_s^{(*)} \ell \nu$ decays is evaluated by repeating the measurement with different sets of model parameters, as specified in Ref. [38]. The total systematic uncertainty due to form factor modeling is given by the quadratic sum of the uncertainties from all decay modes and does not exceed 1%.

The signal efficiencies are studied in bins of three distributions: the lepton momentum, the $D_s$ momentum, and the angle between the reconstructed $D_s$ meson and the lepton in the CM system. A re-calculation of the average efficiencies based on the observed data yields changes the signal by at most 3.1%.

The modeling of the opposite-$B_{(s)}$ component is studied in same-sign $D_s^+ \ell^+$ control samples. The same-sign selection ensures that these samples contain only opposite-$B_{(s)}$ combinations. Compared to the $D_s^{(*)-} \ell^+$ samples, the relative contribution of $B_s$ decays is enhanced in this control sample. Two components of the opposite-$B_{(s)}$ sample are distinguished: (1) primary leptons and (2) secondary leptons and hadron tracks misidentified as leptons. Scale factors for the normalisation of these two MC components are determined from fits to the $p_T^\ell$ distributions of the $D_s^+ \ell^+$ samples. The obtained scale factors are in agreement within the fit uncertainties of about 10%. A variation of the normalisations of the two components in the $D_s^{(*)-} \ell^+$ samples within this 10% uncertainty changes the signal yields between 1.0% and 2.5%, depending on the reconstructed channel. We also vary the fraction of $B_s$ decays in the opposite-$B_{(s)}$ component by 20%, corresponding to the uncertainty of the $B_s$ production rate, $f_s$ [31]. The resulting change of the signal yields is less than 0.2%. The shape uncertainty of the opposite-$B_{(s)}$ component is evaluated in a data-driven way by using again the $D_s^+ \ell^+$ samples, from which the event yields are determined in...
the three counting regions with the identical procedure as applied in the measurement. We calculate the ratios of data and MC yields for each counting region. These ratios range from 0.86 to 0.91 for electrons and from 0.96 to 0.97 for muons. We then modify the MC predictions for the opposite-\(B_{(s)}\) component in the \(D_s^+\ell^+\) simulation accordingly and study the impact on the measurement. The results change by less than 0.4%, so an uncertainty of 1% on the modeling of the opposite-\(B_{(s)}\) component is a reasonable estimate, considering the differences between the \(D_s^+\ell^+\) control samples and the \(D_s^-\ell^+\) signal samples. The described approach cannot be transferred to the \(D_s^+\ell^-\) measurements because of the smaller sample sizes. However, the composition of the \(D_s^-\ell^+\) sample and hence the same uncertainty is assigned.

The decays contributing to the same-\(B_{(s)}\) background component can be grouped into four classes with the corresponding fraction in the electron/muon channel given in parentheses: \(B_{(s)}\) → \(D_{s}^{(*)}\)X, decays (70%/48%), leptons stemming from \(\tau\) produced via \(B_s\) and \(D_s\) decays (21%/16%) and hadrons misidentified as leptons (9%/34%). There are no significant differences in the composition between the \(D_s^-\ell^+\) and the \(D_s^+\ell^+\) channels. We vary the fraction of leptons from \(\tau\) decays and the fraction of misidentified hadrons by \(\pm 50\%\) and take half the difference of the resulting signal yields as the systematic uncertainty, which is below 1% for all measurements. Potential modeling uncertainties of the same-\(B_{(s)}\) component are assumed to be covered by the large variation of the composition.

We estimate the impact of the uncertainty on the different \(B_s\) production channels at the \(\Upsilon(5S)\) energy by scaling the \(B_s\bar{B}_s\) component up and down by 30% and assign half of the change in the signal yield as the systematic uncertainty of 0.1% and 0.3% for the \(D_s^-\ell^+\) and \(D_s^+\ell^+\) modes, respectively. The beam energy is conservatively varied by \(\pm 3\text{ MeV}\) and signal yield variations of 1% and 0.5% are observed for the \(D_s^-\ell^+\) and \(D_s^+\ell^+\) modes, respectively.

**RESULTS AND DISCUSSION**

The semi-inclusive semileptonic \(B_s\) branching fractions are calculated from Eq. (3). Since the \(D_s\) → \(K^+K^-\pi^+\) reconstruction mode is also used in the determination of \(N_{B_s}\), the \(B(D_s^+ \rightarrow K^+K^-\pi^+)\) branching fraction cancels out. Using the branching fraction ratio \(B(D_s^+ \rightarrow \phi\pi^+)/B(D_s \rightarrow K^+K^-\pi^+) = (41.6 \pm 0.8)\%\) and the branching fraction \(B(D_s^+ \rightarrow D_s\gamma) = (94.2 \pm 0.7)\%\) [31], we obtain the semi-inclusive branching fractions:

\[
\begin{align*}
D_s X\ell\nu & : [8.1 \pm 0.3(stat) \pm 0.6(syst) \pm 1.4(ext)]\%, \\
D_s X\mu\nu & : [8.3 \pm 0.3(stat) \pm 0.6(syst) \pm 1.5(ext)]\%, \\
D_s^* X\ell\nu & : [5.2 \pm 0.6(stat) \pm 0.4(syst) \pm 0.9(ext)]\%, \\
D_s^* X\mu\nu & : [5.7 \pm 0.6(stat) \pm 0.4(syst) \pm 1.0(ext)]\%.
\end{align*}
\]

The first uncertainty is the statistical uncertainty of the data and MC samples, the second is the systematic uncertainty of the measurement, and the last uncertainty is due to the external measurements of \(N_{B_s}, B_{s}\) and \(B(D_s^+\gamma)\). The electron and muon sample are statistically independent because only one candidate is selected per event. Taking into account that the systematic uncertainties are all correlated except the one for lepton identification, we calculate the combination of the measurements as weighted averages:

\[
\begin{align*}
D_s X\ell\nu & : [8.2 \pm 0.2(stat) \pm 0.6(syst) \pm 1.4(ext)]\%, \\
D_s^* X\ell\nu & : [5.4 \pm 0.4(stat) \pm 0.4(syst) \pm 0.9(ext)]\%.
\end{align*}
\]

The obtained \(B_s \rightarrow D_s X\ell\nu\) branching fraction can be compared to the difference between the inclusive branching fraction, \(B(B_s \rightarrow X_s\ell\nu)\), and the branching fraction of the \(D_s^{*}\ell\nu\) modes, where the \(D_s^{*}\) does not decay to a \(D_s\) meson. The value of \(B(B_s \rightarrow X_s\ell\nu)\) is estimated to be \((10.0 \pm 0.4)\%\), using the branching fraction \(B(B^0 \rightarrow X_s\ell\nu)\) [31, 46], an estimate for the ratio of the semileptonic widths of the \(B_s\) and \(B^0\) meson, \(\Gamma_{s1}(B_s)/\Gamma_{s1}(B^0) = 0.99\) [47] and the measured lifetimes of the \(B^0\) and \(B_s\) mesons [31].

We assume that only the semileptonic decay modes with \(D_s \rightarrow \gamma\) and \(D_s \rightarrow \pi\) mesons do not contain \(D_s\) mesons in the final state. We obtain the estimate,

\[
\begin{align*}
B_{est}(B_s \rightarrow D_s X\ell\nu) & = B(B_s \rightarrow X_s\ell\nu) \cdot [1 - B(B_s \rightarrow D_s X\ell\nu)/B(B_s \rightarrow X_s\ell\nu)] \\
& = (9.1 \pm 0.4)\%,
\end{align*}
\]

where the ratios \(B(B_s \rightarrow D_s X\ell\nu)/B(B_s \rightarrow X_s\ell\nu) = [3.3 \pm 1.0(stat) \pm 0.4(syst)]\%\) and \(B(B_s \rightarrow D_s X\ell\nu)/B(B_s \rightarrow X_s\ell\nu) = [5.4 \pm 1.2(stat) \pm 0.5(syst)]\%\) were measured at LHCb [45]. The result of our measurement is in agreement with the estimate, \(B_{est}(B_s \rightarrow D_s X\ell\nu)\). The rate of \(B_s \rightarrow D_s^{*}\ell\nu; D_s^{*} \rightarrow D_s^* X\) decays can be constrained from the comparison between the measured semi-inclusive branching fraction, \(B(B_s \rightarrow D_s^* X\ell\nu)\) with the exclusive theory predictions for \(B(B_s \rightarrow D_s^* \ell\nu)\). For example, using the prediction from Ref.[8], one obtains \(B(B_s \rightarrow D_s^{*}\ell\nu; D_s^{*} \rightarrow D_s^* X) < 2.0\%\) at the 90% confidence level.
The measurement can also be used to determine $N_{B_s,B_s}$ using the estimate of the $B_s \to D_s X \ell \nu$ branching fraction from Eq. (10):

$$N_{B_s,B_s} = \frac{N_{\text{sig}}/\epsilon}{2B_{\text{est}}(B_s \to D_s X \ell \nu)}.$$  (11)

For $N_{\text{sig}}/\epsilon$, we insert the weighted average of the electron and muon modes, $N_{\text{sig}}/\epsilon = [26.7 \pm 0.7(\text{stat}) \pm 2.0(\text{syst})] \times 10^6$; for $B(D_s \to \phi(K^+K^-)\pi^+)$, we use the value $(2.24 \pm 0.10)\%$ [31]. We obtain $N_{B_s,B_s} = [6.53 \pm 0.17(\text{stat}) \pm 0.49(\text{syst}) \pm 0.41(\text{ext})] \times 10^6$, corresponding to the cross section $\sigma(e^+e^- \to B_s^{(*)}\bar{B}_s^{(*)}) = [53.8 \pm 1.4(\text{stat}) \pm 4.0(\text{syst}) \pm 3.4(\text{ext})]/\text{pb}$ at the CM energy $\sqrt{s} = 10.86\text{GeV}$. The first two uncertainties are the statistical and systematic uncertainties from the measurement, respectively, and the last uncertainty is due to $B(D_s \to \phi(K^+K^-)\pi^+)$ and $B_{\text{est}}(B_s \to D_s X \ell \nu)$. The obtained result is in agreement with $N_{B_s,B_s} = (7.1 \pm 1.3) \times 10^6$ obtained by Belle with a different technique [23] and has a significantly improved precision.

**SUMMARY**

We have presented the first measurements of the semi-inclusive branching fractions of $B_s \to D_s X \ell \nu$ and $B_s \to D_s^{*} X \ell \nu$ decays. The measured branching fractions are $B(B_s \to D_s X \ell \nu) = [8.2 \pm 0.2(\text{stat}) \pm 0.6(\text{syst}) \pm 1.4(\text{ext})]/\%$ and $B(B_s \to D_s^{*} X \ell \nu) = [5.4 \pm 0.4(\text{stat}) \pm 0.4(\text{syst}) \pm 0.9(\text{ext})]/\%$. In addition, the analysis of these decays provides the currently most precise estimate of the $B_s^{(*)}\bar{B}_s^{(*)}$ production cross-section at the CM energy $\sqrt{s} = 10.86\text{GeV}$: $\sigma(e^+e^- \to B_s^{(*)}\bar{B}_s^{(*)}) = (53.8 \pm 1.4(\text{stat}) \pm 4.0(\text{syst}) \pm 3.4(\text{ext}))/\text{pb}$.

[22] The value $N_{B_s\bar{B}_s} = (3.90 \pm 0.69) \times 10^5$ was obtained by the Belle Collaboration with the method described in A. Drutskoy et al. [Belle Collaboration, Phys. Rev. Lett. 98, 052001 (2007).]
[29] Throughout this paper, the convention $c = 1$ is used.
