7. **Running head:** Changes in bone mineral density in the year after critical illness

8. **Descriptor:** ICU Management / Outcome

9. **Word count:** 2903 words

10. **“At a Glance Commentary”**

   - **Scientific Knowledge on the Subject:** Current evidence suggests critical illness, with its associated immobilization, inflammation, and endocrine dysfunction, is associated with increased bone turnover, loss of bone mineral density, and an increased risk of fragility fracture. However, prospective evidence describing the long-term relationship between critical illness and bone loss is needed to establish the rationale for intervention.

   - **What This Study Adds to the Field:** We report a significant decrease in bone density in the year after ICU admission compared with controls, a significantly increased risk of future fracture, and a typical pattern of bone turnover consistent with accelerated resorption. Our findings suggest that critical illness may trigger increased bone resorption and bone loss, and provide impetus for future interventional studies aimed at decreasing such loss.

11. "This article has an online data supplement, which is accessible from this issue's table of content online at [www.atljsjournals.org](http://www.atljsjournals.org)"
ABSTRACT (249 words)

Rationale: Critical illness may be associated with increased bone turnover and loss of bone mineral density. Prospective evidence describing long-term changes in bone mineral density after critical illness is needed to further define this relationship.

Objectives: To measure the change in bone mineral density and bone turnover markers in patients one year after critical illness compared to population-based controls.

Methods: We studied adult patients admitted to a tertiary intensive care unit (ICU) and requiring mechanical ventilation for at least 24 hours. We measured clinical characteristics, bone turnover markers and bone mineral density during admission and one year after ICU discharge. We compared change in bone mineral density to age and sex-matched controls from the Geelong Osteoporosis Study.

Measurements and Main Results: Sixty-six patients completed bone mineral density testing. Bone mineral density decreased significantly in the year after critical illness at both femoral neck and anterior-posterior spine site. The annual decrease was significantly greater in the ICU cohort compared to matched controls (anterior-posterior spine -1.59%, 95% CI -2.18, -1.01, p<0.001, femoral neck -1.20%, 95% CI -1.69, -0.70, p <0.001). There was a significant increase in 10-year fracture risk for major fractures (4.85+5.25 vs 5.50+5.52, p<0.001) and hip fractures (1.57+2.40 vs 1.79+2.69, p=0.001).
The pattern of bone resorption markers was consistent with accelerated bone turnover.

**Conclusions:** Critically ill patients experience a significantly greater decrease in bone mineral density in the year after admission compared to population-based controls. Their bone turnover biomarkers pattern is consistent with increased rate of bone loss.

**Keywords:** Critical illness, long-term outcomes, osteoporosis, fracture, bone loss, bone mineral density, bone turnover markers.
INTRODUCTION

Compared to their pre-illness status and general population controls, survivors of critical illness face increased mortality\(^1\)\(^-\)\(^4\), physical\(^1\)\(^,\)\(^5\)\(^-\)\(^7\), and cognitive impairment\(^8\)\(^-\)\(^10\), and psychological distress\(^11\)\(^-\)\(^13\). A specific area where critical illness may adversely affect the well-being of survivors relates to an increased risk of fragility fracture\(^\text{14,15}\). However, unlike other aspects of post-critical illness recovery, this risk has not been repeatedly explored.

Osteoporosis is a chronic progressive disease and major public health issue\(^16\), characterized by low bone mass, micro-architectural bone disruption, and skeletal fragility leading to fracture\(^17\). The lifetime risk of osteoporotic spine, hip, or wrist fracture is 30-40% in developed countries, and the lifetime risk of hip fracture is one in six in white females\(^18\), with significant associated health burden of mortality, morbidity, and cost\(^19\)\(^,\)\(^20\). However, as few as 13-27% of patients with osteoporosis are treated following a fragility fracture, suggesting osteoporosis remains an under diagnosed disease\(^21\)\(^,\)\(^22\).

Critical illness, with its associated immobilization, inflammation, and endocrine dysfunction, may be associated with increased bone turnover\(^23\)\(^-\)\(^32\), loss of bone mineral density (BMD)\(^33\), and an increased risk of fragility fracture\(^\text{14,15}\). Critical illness associated increase in bone turnover and subsequent fragility fracture could contribute to long-term morbidity and mortality, and is a potential target for intervention\(^34\). However, prospective evidence describing the relationship between critical illness and bone loss is needed to establish the rationale for intervention. Accordingly, the aim of this study was to
describe the changes in BMD and bone turnover markers (BTMs) in men and women in the year after critical illness, compared to population based age and sex controls.

MATERIALS AND METHODS

Design, ethics and consent

We performed a prospective observational cohort study in a tertiary regional Intensive Care Unit (ICU) in Geelong, Australia, between February 2010 and September 2014. Prior to commencement approval was obtained from the Barwon Health Human Research Ethics Committee. Written informed consent was obtained prior to inclusion in the study. Participants were compared to matched population based controls from the Geelong Osteoporosis Study.

Study population and controls

Adult (age greater than 20 years) patients admitted to the ICU during the study period, and with duration of mechanical ventilation greater than 24 hours were considered eligible for enrolment in the study. The control population was obtained from the Geelong Osteoporosis Study (GOS)\textsuperscript{35}, a random population-based sample from the Australian Commonwealth Electoral Rolls. Additional details on exclusion criteria and GOS are provided in an online data supplement.

Data Collection

Data collected included demographics, osteoporosis risk factors, information relating to critical illness and ICU interventions, ICU and hospital length of
stay, survival, discharge destination, quality of life (EQ VAS; EuroQol visual analogue scale where own health rated “today” on a scale from 0 “worst imaginable health to 100 “best imaginable health”)\textsuperscript{36}, serum biochemistry, serum bone formation marker: type 1 N-terminal procollagen, serum bone resorption marker: collagen type 1 cross-linked c-telopeptide, and BMD. Additional detail on the measurement of serum BTMs and BMD are provided in an online data supplement.

Data were collected at three separate time points, ICU baseline (demographic data, clinical information, BTMs), post-ICU discharge (BMD) and 1-year post-ICU discharge (repeat BMD, BTMs, biochemistry, EQ VAS, accommodation). Details of operating procedure are provided in Appendix 1.

BMD was presented as an absolute value (g/cm\textsuperscript{2}), annualised percentage (difference between BMDs divided by initial BMD calculated as an annualised rate), and categorised as normal (T-score > -1.0), osteopenic (T-score -2.5 to -1.0), or osteoporotic (T-score <-2.5). The T-score is the number of standard deviations above or below the young adult mean, based on WHO criteria\textsuperscript{37} with cut-off values calculated from the Australian reference ranges\textsuperscript{38,39}. Fracture risk assessment was performed for each ICU participant who completed both BMD studies using the Australian version of the FRAX\textsuperscript{®} fracture risk assessment tool, an algorithm developed by the World Health Organization (WHO)\textsuperscript{40} that combines clinical risk factors with or without femur BMD to estimate 10-year probability of hip and major osteoporotic fracture.
Outcomes
The primary outcome was annualised percentage change in BMD (lumbar spine and dual femoral neck) for the year after ICU discharge compared to matched population controls. Secondary outcomes were restricted to the ICU cohort and included osteoporosis classification, fracture risk assessment, change in BTMs, and analysis of factors associated with change in BMD.

Statistical analysis
ICU patients who completed both BMD measurements were matched to GOS controls by age, sex, and BMI, in a one-to-four fashion using Mahalanobis weights, without replacement. Continuously normally distributed data were reported as mean (+standard deviation), whereas non-parametric data were reported using median (interquartile range [IQR]) or frequency distribution. Results were calculated as total and percentage change, with the difference in change and 95% CIs calculated using profile likelihood methods, and p-values calculated from the likelihood ratio test. The primary outcome was analysed using Analysis of Covariance, and a two-sided p-value of 0.05 was considered to be statistically significant. Additional information relating to statistical analyses are provided in an online data supplement.

RESULTS
Patient enrolment
We screened 686 patients and enrolled 138. Of these, 48 (34.8%) withdrew before completing the 1-year BMD measurement, and 24 (17.4%) died before the 1-year BMD measurement, leaving a final cohort of 66 (47.8%) for
analysis (Figure 1).

Baseline characteristics
Baseline patient characteristics including osteoporosis risk factors, critical illness severity, biochemistry, BTMs, key interventions and major outcomes are presented in Table 1. Across all three groups, osteoporotic risk factors were relatively common with 58 (42.0%) of patients having at least one factor.

In the 66 patients assessed, we found a significant decrease in BMD in the year after ICU discharge. This decrease was present at both femoral neck and anterior-posterior spine assessment (Table 2). When stratified by sex, a significant decrease in BMD was observed in females at both sites, and in males at femoral neck only (Table 2). The mean baseline BMD of the ICU cohort and controls were similar after matching at both dual femur and anterior-posterior spine (supplement table 1).

Primary outcome
The annual decrease in BMD was significantly greater in the ICU cohort compared to matched controls (Table 3). The annual decrease in BMD in the year after ICU was 1.48 \( \pm \) 4.37\% (anterior-posterior spine) and 1.72 \( \pm \) 4.37\% (femoral neck), compared to an increase of 0.11\( \pm \) 1.12\% (anterior-posterior spine) and a decrease of 0.53 \( \pm \) 1.07\% (femoral neck) in controls. This represents a difference in annual change in BMD of -1.59\% (95\% CI -2.18, -1.01, \( p < 0.001 \)) at anterior-posterior spine, and -1.20\% (95\% CI -1.69, -0.70, \( p <0.001 \)) at femoral neck in the ICU cohort compared to controls.
difference was significantly greater in females at both AP spine and femoral neck, while in males it was significantly greater at femoral neck only (Table 3).

Secondary outcomes

Overall, in the year after ICU there was a significant decrease in serum collagen type 1 cross-linked c-telopeptide (median 579 ng/L [397,894] vs 306 ng/L [202,554]; p<0.001), and a significant increase in serum type 1 N-terminal procollagen (median 31.0 ug/L [20.5, 49.8] vs 44.0 ug/L [31.2,73.9]; p=0.04) (Table 4). When stratified by sex and compared to population reference levels, the median collagen type 1 cross-linked c-telopeptide levels exceeded the 3rd interquartile reference values for females (ICU 654.0 ng/L [IQR 478.5, 1165] vs GOS 338 ng/L [IQR 212, 499] and males (ICU 483.0 ng/L [IQR 382.0, 851.0] vs GOS 328 ng/L [IQR 235, 459]), and returned to normal by 1-year. In contrast, type 1 N-terminal procollagen significantly increased but remained within normal levels for males and females (Table 4). Over the year from critical illness to follow-up there was a significant increase in median vitamin D concentration (43.0 nmol/L [31.0,52.8] vs 55.0 mmol/L [46.0,71.0], p<0.001), elevated median parathyroid hormone levels at baseline that did not significantly change (8.1 pmol/L [4.0,13.8] vs 5.4 pmol/L[4.2,9.4], p=0.15), and a significant increase in median adjusted calcium levels (2.0 mmol/L [1.8,2.1]) vs 2.2 (2.2,2.3), p<0.0001).

The percentage of patients with an osteoporotic or osteopenic T-score did not change significantly from baseline to one-year after ICU discharge (45.3% vs 54.7%, p=0.08), although the estimated 10-year fracture risk for both all major
fractures (4.85±5.25 vs 5.50±5.52, p<0.001) and hip fractures specifically (1.57±2.40 vs 1.79±2.69, p=0.001) significantly increased (Table 4). Finally, 66.7% of females and 44.1% of males were classified as either osteoporotic or osteopenic at 1-year, and the 10-year fracture risk was highest in females.

DISCUSSION

Key findings

We performed a prospective observational study in critically ill mechanically ventilated patients to measure the changes in BMD and bone turnover markers in the year after ICU admission. We found that these patients experienced a significant decrease in BMD in the year after ICU admission, and this was significantly greater than matched controls. Moreover, they carried a significantly increased estimated risk of future fracture. These clinical events were associated with a specific pattern of bone turnover markers. This pattern was suggestive of increased bone resorption with no commensurate response in bone formation during critical illness, followed by normalization of resorptive activity but no compensatory increased formation activity a year later.

Relationship to previous studies

To our knowledge, the only previous report of BMD changes after ICU described a significant decrease in calcaneal BMD over a 10-day period in patients with Acute Respiratory Distress Syndrome (ARDS) compared to ventilated non-ARDS patients. However, BMD undergoes relatively small changes over time of a magnitude similar to measurement error therefore
follow-up over longer periods is recommended, making a one year change in BMD the standard for interventional research studies\textsuperscript{41-45}. This makes our observations relevant to potential intervention in the future.

Bone turnover markers are an important tool to assess progression of osteoporosis, fracture risk, and treatment response\textsuperscript{46,47}. We measured type 1 N-terminal procollagen, a bone formation marker synthesized by osteoblasts and released during the processing of type I procollagen into collagen, and the bone resorption marker collagen type 1 cross-linked c-telopeptide, a product of collagen degradation. Both markers correlate with corresponding histomorphometric parameters of bone formation and resorption, and have been identified as the most promising bone turnover markers by the Joint International Bone Markers Standards Working Group\textsuperscript{46}. We observed a change from increased bone resorption during critical illness, to normal bone resorption with increasing bone formation over the subsequent year, consistent with previous studies reporting increased bone resorption markers\textsuperscript{24,26,29-31,48,49}, increased serum osteoclast precursors\textsuperscript{32}, increased bone formation, and decreased osteocalcin during critical illness compared to controls\textsuperscript{26,28,29,49}. Overall these findings suggest changes associated with critical illness of a magnitude similar to that described in postmenopausal females, or metabolic bone disease\textsuperscript{29,47,50,51}. The interpretation of bone turnover markers during critical illness is complex, however as levels are affected by a number of factors including age, gender, co-existing disease, inflammatory markers, and medications, particularly glucocorticoids\textsuperscript{26,28,49,52,53}. This study was unable to analyse these relationships due to its limited sample size.
Abnormalities in the vitamin D-parathyroid-calcium axis during critical illness, and the association with increased illness severity, length of stay, and mortality, and the effects of vitamin D supplementation on inflammatory markers and outcomes have been described \textsuperscript{54-64}. We observed a pattern of vitamin D insufficiency, increased parathyroid hormone release, and hypocalcaemia, during critical illness and normalisation at one-year follow-up. Vitamin D deficiency with resultant secondary hyperparathyroidism and prolonged immobilization may increase the risk of excessive bone resorption; however treating critically ill patients with vitamin D resulted in inconsistent effects on bone turnover markers, suggesting that accelerated bone turnover is multifactorial \textsuperscript{29,48}.

Over half of survivors in our study had BMD in the osteopenic or osteoporotic range, higher than local population levels, with the Geelong Osteoporosis Study reporting one-fifth of females greater than fifty years of age have BMD in the osteopenic range, and 1 in 6 have osteoporosis \textsuperscript{65}. Although the proportion of patients with BMD below normal values did not change significantly during the year after critical illness, the use of BMD category alone has limitations for fracture prediction, as over half of fragility fractures arise from the population of individuals with osteopenia, rather than the higher risk but smaller population with osteoporosis \textsuperscript{65-67}. This has led to the development of fracture risk prevention models that incorporate clinical factors and BMD, including the FRAX\textsuperscript{®} fracture risk assessment tool \textsuperscript{40}. In this regard, we observed a significant increase in 10-year probability of hip and major osteoporotic fracture in the year after critical illness, consistent with a previous observation of increased fracture prevalence in older females.
following critical illness compared to population-based controls \cite{14}.

**Study implications**

This study implies that critical illness is associated with increased bone turnover, loss of BMD and increased risk of fragility fractures for up to one year after ICU discharge. Such reduced bone mass and increased bone loss in the year following critical illness, particularly in female survivors, has not been previously described and further implies that such patients may be at particular risk. Moreover, in such female patients it also implies that anti-resorptive therapy to prevent bone loss, reduce fracture risk, and possibly improve survival should be carefully considered. Finally, this study provides a rationale for, and essential information towards, the design of pilot interventional trials aimed at decreasing bone resorption using BMD at one year as the primary outcome. The notion that intervention may be effective is supported by short term studies such as a retrospective case series describing a reduction in urine N-telopeptide in long-term ventilated patients treated with pamidronate\cite{48}, and a randomised trial of 20 chronic critically ill postmenopausal females reporting a decrease in serum collagen type 1 cross-linked c-telopeptide and increase in osteocalcin with ibandronate compared to placebo\cite{68}. In addition multimodal therapies, including physical therapies and rehabilitation warrant investigation in this population\cite{69}.

**Strengths and limitations**

Our study has several strengths. For the first time, we collected detailed information, including risk factors, relating to bone mass in a cohort of ICU survivors over a prolonged period. This is important as establishing the
presence of bone loss after critical illness requires extended observation. We measured biomarkers of bone turnover to establish broad relevance to similar biomarker studies. For the first time, we followed up a cohort of critically ill patients for one year to establish the long-term changes in BMD. Moreover, we were able to identify clear and logical changes in BMD over time, which were particularly striking in females. Finally, and also for the first time, we compared our cohort with age and sex matched controls from a well described population-based sample from the same community.  

There are limitations to this study. The loss of over half of the participants enrolled due to withdrawal or death made it impossible to develop a robust predictive model for specific additional risk factors, and restricts generalizability of the findings. However, as expected, female sex was clearly associated with greater loss of BMD. Furthermore despite a higher than expected rate of death and loss to follow-up, the greater than expected decline in BMD resulted in sufficient data to demonstrate differences in the primary outcome that were statistically significant and clinically relevant. A larger cohort would provide the ability to identify further risk factors, but such demanding work can only be justified if studies such as ours provide sufficient preliminary data to support its conduct. Comparison of BMD in ICU patients to a population-based control group rather than a hospital-based control group means we cannot exclude that hospitalisation per se (instead of ICU admission alone) may be associated with increased loss of BMD. However, the decrease in BMD seen in these patients constitutes the necessary initial evidence to conduct such larger studies. Measurement of BMD at ICU
discharge and again at one-year does not allow for the observation of non-linear changes in bone density, for example it is possible an early rapid loss of bone density occurred in the months after critical illness, with subsequent recovery. However one year change in BMD is the standard for interventional research studies\textsuperscript{41-45}.

Also, we have demonstrated an association between critical illness and greater decline in BMD, but were unable to separate the effects of pre-critical illness factors from critical illness per se. Pre-critical illness chronic disease, frailty, and worsening functional trajectory are common in critically ill patients, and are associated with trajectory and degree of recovery \textsuperscript{70-73}. The matching of the ICU cohort and the GOS controls by gender and age resulted in similar baseline BMDs, refuting the notion that the ICU cohort had lower bone density than controls at the time of admission. This may be explained by the characteristics of the cohort that completed the study. By definition they had 100\% one-year survival, reported high quality of life, and 95\% lived independently one-year after ICU discharge. This pattern is most consistent with a minimal disability functional trajectory, or a non-frail population \textsuperscript{70,71}. Finally although long-term ICU recovery trials would ideally include prospectively collected pre-ICU trajectory data \textsuperscript{73-75}, critical illness may act as a marker for under-diagnosed disease burden irrespective of causality \textsuperscript{73}.

Conclusions

We performed a prospective observation study in critically ill mechanically ventilated patients to measure the changes in BMD and bone turnover
markers in the year after ICU admission. We found that these patients experienced a significant decrease in bone density in the year after ICU admission compared with controls; carried a significantly increased risk of future fracture and had a typical pattern of bone turnover consistent with accelerated resorption. Our findings suggest that critical illness may trigger increased bone resorption and faster loss of BMD and provide impetus for future interventional studies aimed at decreasing such loss.

Appendix / Supplement Files

Supplementary Methods

Exclusion criteria: Exclusion criteria included active malignancy, existing neurological illness with impaired weight bearing, inability to lie flat, metabolic bone disease, pregnancy, weight greater than 120 kilograms, and considered unlikely to survive by the treating intensivist. Patients who had multiple ICU admissions during the study period were included for their first ICU admission only. Patients not enrolled in the study by day 7 of mechanical ventilation were no longer considered for inclusion in the study.

Geelong Osteoporosis Study description: The Geelong Osteoporosis Study is a random population-based sample from the Australian Commonwealth Electoral Rolls recruited between 1993 and 1997 (women) and 2003 to 2008 (men), for a geographically well defined region, surrounding Geelong, in south-eastern Australia called the Barwon Statistical Division. As voting is compulsory in Australia, the electoral roll provides a comprehensive listing of adults (age > 18 years). Age-stratified random samples of 1494 women (age range 20-94 years) and 1540 men (age range 20-97 years) were enrolled, with a minimum of 100 in each 5-year age stratum between ages 20 and 69, and a minimum of 200 in the age 70-79 year group, and the over 80 year group. In this control population, BMD measurements are performed second yearly in the female cohort and five yearly in the male cohort.
Bone mineral density and serum bone turnover marker measurement description: BMD was measured by dual energy x-ray absorptiometry (DXA) (Lunar; GE Healthcare, Madison, Wis, USA), at the proximal femur and lumbar spine. Short-term precision in vivo was 1.6% for the femoral neck and 0.6% for the lumbar spine. The serum bone turnover markers collagen type 1 cross-linked c-telopeptide and type 1 N-terminal procollagen were collected the morning after enrolment with routine early morning blood tests, and measured using the automated Roche Modular Analytics E170 analyser. Serum collagen type 1 cross-linked c-telopeptide limit of detection was 10 ng/L with inter-assay coefficient of variations (CVs) of 6.5% at 361 ng/L, 3.8% at 816 ng/L and 3.4% at 3304 ng/L (n = 10). Serum type 1 N-terminal procollagen inter-assay CVs were 4.9% at 73 µg/L, 2.6% at 392 µg/L, and 2.1% at 768 µg/L (n = 10) with a limit of detection of 5 µg/L. Bone turnover markers were compared to reference ranges derived from an Australian population sample.

Statistical analysis description: ICU patients who completed both BMD measurements were matched to GOS controls by age, sex, and BMI, in a one-to-four fashion using Mahalanobis weights, without replacement. Mahalanobis weighting was chosen to account for correlation. The average treatment effect for those participants admitted to the ICU was estimated via linear regression including the covariates used for matching, an indicator variable for whether the participant was admitted to the ICU or was a (GOS) population control, and a random effect to account for correlation induced by the matching. Ninety-five percent confidence intervals (95% CIs) were
calculated for the difference by profile likelihood, with p-values from the likelihood ratio test.

The annual decline in lumbar spine in the GOS population is normally distributed, with a standard deviation of 0.06% at the lumbar spine in males, and 0.25% at the lumbar spine in females. In the absence of any existing data describing long-term BMD changes following critical illness, a global effect size of 50% of one standard deviation was chosen to be clinically significant as it equates to a 12% difference across the range of each variable. In order to have a 90% power (2-sided p-value of 0.05) to detect an effect size of 50% of one standard deviation, 84 subjects are required. Allowing for potential deaths (20%) and dropouts (20%), 138 subjects were recruited.

Data were analysed using R version 3.1.3 (R Core Team 2015) and a two-sided p-value of 0.05 was considered to be statistically significant. Continuously normally distributed data were reported as mean (+standard deviation), whereas non-parametric data were reported using median (IQR) or frequency distribution. The primary outcome was analysed using Analysis of Covariance. Results were calculated as total and percentage change, with the difference in change and 95% CIs calculated using profile likelihood methods, and p-values calculated from the likelihood ratio test.
Appendix 1: Study operating procedures

Softer Study Procedures
>24 hrs to <168 hrs duration of mechanical ventilation
Enrolment
Inclusion criteria met, consent obtained

Study procedures
Baseline and demographic data
Biochemistry and BTM (serum PINP, CTx, Vit D, PTH, albumin, calcium, phosphate, creatinine)

ICU discharge (ICU discharge to 1-month)
Study procedure
BMD #1

1 year follow-up (1 year post-ICU discharge)
Study procedure
Contact participant
BMD #2
Biochemistry and BTMs (serum PINP, CTx, vitamin D, PTH, albumin, calcium, phosphate, creatinine)
Questionnaire (EQ VAS)

Vitamin D / calcium / anti-resorptive therapy will be offered to participants in accordance with current guidelines and review of results and risk factors by an endocrinologist
