Surgical anatomy of the round window with special reference to cochlear implantation

by

BURKHARD K. H. FRANZ, GRAEMLNE M. CLARK and DAVID M. BLOOM (Melbourne, Australia)

Abstract

When the multi-channel cochlear implant electrode is inserted into the scala tympani through the round window the operation is best performed via a posterior tympanotomy. The view of the round window membrane, however, is incomplete because of its orientation and the fact that it has a conical shape. Nevertheless, a good view along the basal turn is obtained after the antero-inferior overhang of the round window niche and the crista fenestrae have been removed. It might be damaging to drill away the postero-superior overhang as the osseous spiral lamina lies extremely close to the round window membrane.

Introduction

Different approaches for placing the cochlear implant electrode as close as possible to the nerve fibres have been described (Chouard and MacLeod, 1976; Clark, 1975; Kubik, 1984; Simmons, 1966). The round window as an access for inserting an electrode array has advantages. The surgical approach is relatively easy and the electrode can be placed close to the tonotopically organised auditory nerve fibres in the spiral lamina. Thus the insertion of the electrode into the scala tympani through the round window has been used by many surgeons (Burian et al., 1981; Clark et al., 1979; House and Urban, 1973; Michelson, 1971; Michelson and Schindler, 1981).

Difficulties encountered when inserting an electrode array through the round window using an endaural approach were discussed by Banfai in 1978. With this approach the electrode hit the modiolus and was deflected towards the outer wall before passing along the basal turn. To overcome this difficulty and to obtain a better view along the basal turn of the cochlea the lowest point of the basal turn was recommended for the electrode insertion, the most favourable site being 3–4 mm. in front of the round window.

When inserting an electrode through the round window via a posterior tympanotomy the modiolus is not in the way. The electrode can be passed directly along the basal turn of the cochlea, and it can be inserted an extra few millimeters (Clark et al., 1979). Ideally the electrode insertion via a posterior tympanotomy is performed correctly when the antero-inferior overhang of the round window niche and the crista fenestrae are removed. The postero-superior overhang of the round window niche prevents complete visibility of the window membrane. In order to obtain a better view of the window the surgeon is tempted to remove the obstructing postero-superior overhang. However, in approaching the round window in this fashion there is a risk
The objective of the present study was to show the particular shape of the round window membrane, and the relationship between the round window and the osseous lamina. Furthermore we wanted to establish that the electrode inserted from a posterior tympanotomy would move along the outer wall of the basal turn once the antero-inferior overhang and the crista fenestrae had been removed.

In anatomical textbooks it can be found that the round window niche is formed by the antero-inferior and posterior bony overhang. The posterior overhang, however, does also lie superior to the round window membrane. Therefore this part of the window niche is termed the postero-superior overhang in the following text.

Method
Five temporal bones from the cat, which is our experimental animal, and five human temporal bones were compared macroscopically. For microscopic comparison a right human temporal bone was removed 24 hours after death and fixed in 10 per cent formalin, and a right cat temporal bone was removed after intra-arterial perfusion with phosphate buffered saline containing heparin and followed by Karnovsky's fixative in phosphate buffer. The temporal bones were decalcified in EDTA and embedded in Spurr's resin. The cat temporal bone was sectioned in the midmodiolar plane running through the round window. The human temporal bone was sectioned in the sagittal plane. Sections were stained with haematoxylin-eosin and viewed under a light microscope.

Results
The round window membrane of the human and of the cat has a conical shape with...
a peak directed towards the scala tympani. The conical shape of the round window results from fusion with the base of the primary osseous spiral lamina (Fig. 1). There are three surfaces of the conical cap: two large membraneous ones that gradually form a right angle to each other; and a small bony surface that constitutes the fusion with the osseous spiral lamina. One of the membraneous surfaces of the cone lies in the horizontal plane. This portion forms the posterior part of the round window membrane and is slightly smaller than the anterior portion which lies in a vertical plane.

The conical shape of the round window resembles the tympanic membrane. However, the cone of the round window membrane has a peak that lies off-centre and thereby gives the cone an asymmetric shape. In the cat the conical shape of the round window membrane can be observed with the operating microscope as the membrane is not hidden underneath bony structures. In the human the round window membrane is difficult to see as most of it is covered by the postero-superior and antero-inferior overhang.

In approaching the round window from a posterior tympanotomy the surgeon faces the anterior portion of the membrane that lies in a vertical plane. The posterior portion of the membrane that lies in the horizontal plane cannot be seen as it is covered completely by the postero-superior overhang (Figs 1 and 2).

In the human and in the cat the horizontal portion of the round window membrane lies extremely close to the osseous spiral lamina (Figs. 1 and 3). In the human the distance between the round window membrane and the osseous spiral lamina is only 0.1 mm. at the posterior periphery; however, the distance increases a little towards the centre of the round window to about 1 mm.

From the posterior tympanotomy the very beginning of the outer wall of the basal turn cannot be seen unless the crista fenestrae is removed. The crista fenestrae narrows the basal turn in contrast to the gradually widening basal turn of the cochlea further in (Fig. 4).

For better demonstration the postero-superior and the antero-inferior overhang have been removed. bm: basiliar membrane; spl: spiral lamina; sct: scala tympani; rwm: round window membrane, cf: crista fenestrae.

Discussion

The round window was described for the first time in detail by the Italian anatomist Antonio Scarpa in 1772. In 1953 Anson and Bast described extensively the embryologic development of this region. Scarpa called the round window membrane the secondary membrane, because it resembled the primary window, namely the tympanic membrane. He saw a common feature of both windows in their conical shape.

Our microscopical observations showed that the round window of the cat and the human were very similar. However, features were more distinct in the cat than in the human. Macrosopic features appeared slightly rudimentary in the human and were not apparent at first sight, and this was due to a deep round window niche.

In the human there are three important characteristics of the round window niche: firstly, the postero-superior overhang is much smaller than the antero-inferior overhang; secondly, after removal of the postero-superior overhang via a posterior tympanotomy the posterior portion of the round window membrane is still difficult to see as it lies in the plane of vision. This difficulty leads the surgeon to remove more from that overhang; thirdly, the posterior portion of the round window membrane comes extremely close to the osseous spiral lamina.

The round window membrane fuses with the base of the osseous spiral lamina where we find the peak of the cone. From here towards the posterior periphery the membrane and the osseous spiral lamina move away from each other, and the distance reaches about 1 mm. However, at the posterior periphery the osseous spiral lamina, being curved, returns towards the round window membrane, and here the distance is only 0.1 mm. (Figs. 1 and 3).

When the postero-superior overhang is removed the spiral lamina can be traumatised. While the surgeon uses a diamond burr he might not be aware of breaking the spiral lam-

Conclusions

The round window is a convenient access for the electrode insertion in cochlear implants. Approaching the round window from a posterior tympanotomy the surgeon must be aware of the conical shape of the round window membrane, the crista fenestrae, and the osseous spiral lamina hidden beneath the postero-superior overhang of the window niche. A simple and safe procedure is the removal of the antero-inferior overhang. This step is taken prior to the removal of the crista fenestrae. Thereafter the electrode can be inserted along the outer wall of the basal turn of the cochlea.
