Summary
Hypercalcaemia is a very common endocrine condition, yet severe hypercalcaemia as a result of fungal infection is rarely described. There are only been two reported cases in the literature of hypercalcaemia associated with Cryptococcus infection. Although the mechanism of hypercalcaemia in these infections is not clear, it has been suggested that it could be driven by the extra-renal production of 1-alpha-hydroxylase by macrophages in granulomas. We describe the case of a 55-year-old woman with a 1,25-OH D-mediated refractory hypercalcaemia in the context of a Cryptococcus neoformans infection. She required treatment with antifungals, pamidronate, calcitonin, denosumab and high-dose glucocorticoids. A disseminated fungal infection should be suspected in immunosuppressed individuals presenting with hypercalcaemia.

Learning points
- In immunocompromised patients with unexplained hypercalcaemia, fungal infections should be considered as the differential diagnoses;
- Glucocorticoids may be considered to treat 1,25-OH D-driven hypercalcaemia; however, the benefits of lowering the calcium need to be balanced against the risk of exacerbating an underlying infection;
- Fluconazole might be an effective therapy for both treatment of the hypercalcaemia by lowering 1,25-OH D levels as well as of the fungal infection.

Background
Hypercalcaemia is a very common endocrine condition, yet severe hypercalcaemia as a result of fungal infection is rarely described (1,2,3,4).

Case presentation
A 55-year-old woman of Polynesian descent was presented 6 weeks after her second liver transplant with tachycardia and rising inflammatory markers. She had a history of end-stage liver disease due to non-alcoholic steatohepatitis cirrhosis, type 2 diabetes mellitus, obesity, hypertension and recurrent perianal abscesses. Her first liver transplant 4 months prior had failed as a result of acute rejection, hepatic bilomas, recurrent Enterococcus faecium and Pseudomonas aeruginosa bacteraemia and cytomegalovirus viraemia. She was immunosuppressed with cyclosporine 275 mg and mycophenolate 1000 mg twice daily. Her other medications included aspirin 100 mg daily, cholecalciferol 25 mcg daily, sulfamethoxazole/trimethoprim 800/160 mg daily, enoxaparin 40 mg daily, entecavir 0.5 mg daily, valganciclovir 900 mg daily, pregabalin 25 mg twice daily and approximately 40.
units of basal-bolus insulin daily. She was not taking any thiazide diuretics.

A computed-tomography pulmonary angiogram revealed bilateral air space opacities (Fig. 1). Her Cryptococcus antigen titre was greater than 1 in 2560. Culture of bronchial washings demonstrated the growth of *Cryptococcus neoformans*.

The patient was commenced on induction therapy with i.v. liposomal amphotericin 300 mg daily and oral flucytosine 1 g twice daily. While on antifungal treatment, she developed invasive fungal skin lesions over her abdomen and thighs (Fig. 2) with biopsies demonstrating the growth of *Cryptococcus neoformans*. After 4 weeks, she transitioned to consolidation therapy with oral fluconazole 800 mg daily. Ten days later, the patient developed further skin lesions, raising concerns about disease progression and she recommenced i.v. liposomal amphotericin and oral flucytosine at the former doses. A fluorodeoxyglucose PET (FDG-PET) scan demonstrated findings in keeping with disseminated cryptococcosis, with FDG-avid lesions in the lungs as well as substantial s.c. and muscle tissue avidity (Fig. 3).

Three weeks after her presentation, she was noted to have elevated corrected calcium of 2.79 mmol/L (2.10–2.60). Her calcium concentrations were observed and continued to rise steadily. The patient was surprisingly asymptomatic from the hypercalcaemia. She remained alert and oriented and did not experience polyuria or polydipsia. Throughout her hospitalisation she remained ambulant, mobile and had consumed a regular diet without any nutritional or calcium supplementation.

Further investigations when corrected calcium was 3.17 mmol/L demonstrated that the ionised calcium was 1.69 mmol/L (1.12–1.30), the parathyroid hormone 1.1 pmol/L (0.7–4.1), the thyroid stimulating hormone 4.96 mU/L (0.38–5.30), 25-hydroxy-vitamin D (25-OH D) 59 nmol/L and 1,25-dihydroxy-vitamin D (1,25-OH D) 219 pmol/L (50–190). The parathyroid hormone was measured on the Diasorin Liaison (1-84) assay which was subsequently found to report falsely high values at the lower end of the reference range. Her albumin was 35 g/L (35–52) and the estimated glomerular filtration rate was 61 mL/min/1.73 m² (>90).

### Treatment

As the cause of her hypercalcaemia was not immediately apparent, she was observed for several days before treatment with 30 mg of i.v. pamidronate. Despite this, the corrected calcium continued to rise, peaking at 3.82 mmol/L. The patient received a 48 h course of i.v. calcitonin 100 mg 6 h followed by 60 mg of s.c. denosumab.
Outcome and follow-up

The calcium slowly decreased but remained above 3 mmol/L. Two weeks later, the patient had a liver biopsy demonstrating acute liver rejection and was treated with i.v. pulse methylprednisolone. The calcium levels sharply declined and normalised within several days (Fig. 4). There were no granulomas on the skin or liver biopsies.

She was discharged to the rehabilitation unit 4 weeks later and then was discharged home following a further 4 weeks. She remains normocalcaemic and continues on oral antifungals for an ongoing lower limb cutaneous Cryptococcus infection.

Discussion

Hypercalcaemia mediated by 1,25-OH D has been described as a rare complication of fungal infections. There are only two case reports in the literature of hypercalcaemia associated with Cryptococcus neoformans infection (1,2). In both of these cases, the patients were infected with HIV and had a low CD4 lymphocyte count. Whilst the case described by Spindel had disseminated multiorgan Cryptococcus infection (1), Ali et al describe isolated pulmonary Cryptococcus neoformans and Coccidioides immitis infection (2). Both cases had an elevated 1,25-OH D and a peak corrected calcium in the range of 3.30–3.60 mmol/L. Hypercalcaemia was managed with i.v. fluids, antifungal treatment and one of the cases required i.v. pamidronate and hydrocortisone. Resolution of the hypercalcaemia coincided with the resolution of the Cryptococcus infection. Tuberculosis and lymphoma were excluded as alternative causes of hypercalcaemia.

Although the mechanism of hypercalcaemia in these infections is not clear, the fact that 1,25-OH D levels were elevated in all three cases suggest that the hypercalcaemia could be at least partly driven by the extra-renal production of 1-alpha-hydroxylase by macrophages in granulomas (1,3). Indeed, Cryptococcus is known to induce a granulomatous response (5), and granulomas were found in the skin and liver biopsies of the case reported by Spindel (1). A review has suggested that 1,25-OH D may play a role in regulating immune function (4) so this pathway may become activated through adaptive mechanisms. However, there is no data to definitively support this theory.

Management of 1,25-OH D-driven hypercalcaemia includes the restriction of dietary calcium and sunlight exposure (4). Glucocorticoids inhibit 1-alpha-hydroxylase activity in macrophages as well as 1,25-OH D-mediated absorption of calcium from the gastrointestinal tract,

and may also be given. However, the risks of exacerbating an underlying infection need to be carefully considered against the benefit of controlling hypercalcaemia. In our case, methylprednisolone was administered as it was essential for the survival of the liver graft and fortuitously resolved the hypercalcaemia.

In addition to its antifungal effects, fluconazole inhibits 25-hydroxylase and 1-alpha-hydroxylase, and its use in reducing 1,25-OH D levels in a patient with a CYP24A1 mutation has been described (6). In our case, the calcium levels dropped during fluconazole therapy, but this may have been confounded by concurrent calcitonin and denosumab therapy.

In summary, Cryptococcus neoformans is a rare cause of 1,25-OH D-mediated refractory hypercalcaemia which in our case required antifungal treatment, pamidronate, calcitonin, denosumab and high dose glucocorticoid treatment. Hypercalcaemia is a rare complication of disseminated fungal infection, which should be suspected in immunosuppressed individuals.
