Trends in Psychological Distress, Depressive Episodes and Mental Health Treatment-Seeking in the United States: 2001-2012

Ramin Mojtabai and Anthony F. Jorm,
Summary:

Objective: To examine recent trends in psychological distress, depressive symptoms and mental health treatment seeking in the US adult general population.

Methods: Using data from three large general annual population surveys—the National Health Interview Survey (NHIS), Behavioral Risk Factor Surveillance System (BRFSS), and National Survey on Drug Use and Health (NSDUH)—we examined temporal trends in non-specific psychological distress, depressive symptoms and mental health treatment seeking over the 2001-2012 period.

Results: Prevalence of past-month significant psychological distress and past-year depressive symptoms changed little over time. However, the proportion of BRFSS participants reporting poor mental health increased over time—8.7% of the 2011-2012 participants compared to 6.6% of the 2001-2002 participants reported poor mental health for 15 days or longer in the past month and 5.7% vs. 4.6%, respectively, reported poor mental health on all days. A larger percentage of participants in the later period also reported receiving mental health treatments.

Discussion: Despite increases in mental health treatment seeking in the US in the first decade of this century, there is no evidence of a concomitant decrease in prevalence of psychological distress or depression.
The use of mental health services, in general, and psychiatric medications, in particular, dramatically increased in the United States in 1990s. Yet there is no evidence that the prevalence of mental disorders declined over this same period. Indeed, one study based on two large national surveys, the National Longitudinal Alcohol Epidemiologic Survey and the National Epidemiologic Survey on Alcohol and Related Conditions, found a more than two-fold increase in the prevalence of major depressive episodes between 1991–1992 and 2001–2002. Other studies based on the National Comorbidity Survey of 1991-1992 and National Comorbidity Survey-Replication of 2001-2003 found essentially similar prevalence of 12-month depression and other common mental disorders in this period. Nevertheless, these authors and others have noted significant increases in mental health treatment seeking, and especially psychiatric medications in this period. Similar results have been reported from other industrialized countries. These trends are indeed puzzling and raise questions about the effectiveness of mental health treatments and the public health impact of campaigns aimed at increasing treatment seeking.

Much of the past research on trends in psychiatric disorder, distress and mental health treatment seeking in the US has explored these trends in the 1990s. Less is known about trends in more recent years. There is some evidence that the increasing trend in antidepressant medication use in the US may have slowed down and any increase in prevalence of use in the first decade of the century may be attributed to an increase in long-term use of these medications. There is also some evidence of increase in prevalence of self-reported mental health disability in more recent years. However, trends in mental health service use in general and psychological distress need to be further examined.

In this study, we used data from multiple nationally representative population surveys to examine trends in psychological distress and depressive symptoms in the US adult population between 2001 and 2012. We further assessed trends in treatment seeking and perceived unmet need for mental health treatment in this period. This study builds on past research by extending
the years covered to the first decade of the 21st century. The study also improves upon past research by using data from large annual surveys that employed the same measures each year.

METHODS

Samples

Data were drawn from 3 annual national surveys: the National Health Interview Survey (NHIS), the Behavioral Risk Factor Surveillance System (BRFSS), and the National Survey on Drug Use and Health (NSDUH). NHIS is an annual, cross-sectional survey of the non-institutionalized US population conducted by the National Center for Health Statistics. The survey is comprised of a family interview with a knowledgeable adult informant regarding each family member. In addition, a randomly selected adult member was interviewed. The data for this report come from these adult interviews. The final response rates, calculated by multiplying the response rates for family interview and random adult interview, ranged from 61% to 79% over the years, with a median of 71%. A total of 349,852 participants aged 18+ years old participated in the NHIS 2001 to 2012 and comprised the sample for this study.

The BRFSS is a nationally representative phone survey of the U.S. population. The survey incorporates a core module, with questions asked of all participants, and additional specialized modules used in various states in different years. (A more detailed description of BRFSS is available at: http://www.cdc.gov/brfss/). In this study we used data from the 50 states and the District of Columbia for years 2001 to 2012. The response rates to the surveys ranged from 45% to 58%, with a median of 52%. A total of 4,452,059 BRFSS participants aged 18+ were included in this study.

NSDUH is a representative cross-sectional annual survey of US adults in the 50 states and the District of Columbia sponsored by Substance Abuse and Mental Health Services Administration (SAMHSA). The target population was comprised of residents of households, non-institutional group quarters, and civilians living on military bases who were 12 years old or
older. All interviews were conducted in person, using computer-assisted interviewing methods (response rate range=63% to 79%, Median=75%). A total of 452,961 NSDUH participants aged 18+ were included in this study.

Assessments

Psychological distress in NHIS was assessed by K6, a standardized screening instrument developed specifically for use in general population surveys. K6 rating is the summary score of 6 items, assessing nonspecific psychological distress over the past 30 days. Items are rated on a Likert scale from “none” (= 0) to “all the time” (= 4); with a summary score range of 0-24. In a clinical reappraisal study, K6 was shown to have acceptable psychometric properties to detect conditions meeting the criteria of one of the DSM-IV disorders as ascertained by the Structured Clinical Interview for DSM-IV (SCID) and a score of 60 or less on the Global Assessment of Functioning scale (GAF). On the basis of the ROC curve analysis, a score of ≥13 on K6 was selected as the optimal cutpoint to identify psychological distress associated with serious mental illness. This cutpoint is associated with a sensitivity of 0.36, a specificity of 0.92, and a total classification accuracy of 0.92 and equalizes the number of false-positives and false negatives in population samples. More recently, Prochaska and colleagues identified a cut point of ≥6 for “moderate” psychological distress based on treatment seeking patterns in a population sample. Based on these cutpoints, two categories of psychological distress were identified for this study: moderate psychological distress (K6 score ≥6 and <13) and, severe psychological distress (K6≥13).

Major depressive episodes in the past year were assessed in NSDUH using a structured interview based on DSM-IV criteria. Questions were adapted from the depression section of the National Comorbidity Survey Replication and administered by using computer-assisted interviewing methods. In addition, the total number of lifetime depressive episodes and the age of onset of the first episode were assessed. Assessment of major depressive episodes started
in NSDUH 2004. However, the structured interview was conducted with only half of the 2004 sample. Therefore, we limited the analyses for trend to the–year period of 2005-2012 in which assessment was conducted in the full annual sample each year.

*Number of days with poor mental health* was assessed in BRFSS by asking the participants: “Now thinking about your mental health, which includes stress, depression, and problems with emotions, for how many days during the past 30 days was your mental health not good?” Responses were categorized into more than half of the time (≥15 days) and all days (30 days).

*Use of psychiatric medications* was ascertained in NSDUH based on one question asking if the participant had taken medication that were prescribed “to treat a mental or emotional condition” in the past year.

*Contact with mental health professionals* in the past year was assessed in NHIS by asking the participants if during the past 12 months they had seen or talked to a mental health professional such as a psychiatrist, psychologist, psychiatric nurse, or clinical social worker.

*Any mental health treatment* in the past year was assessed in NSDUH based on questions about receipt of outpatient mental health treatment/counseling, inpatient treatment and taking prescription medication. The individual was rated as having received mental health treatment if the person responded positively to questions about either form of treatment.

*Perceived unmet need for care* was defined by a positive response to the following question in NSDUH: “During the past 12 months, was there any time when you needed mental health treatment or counseling for yourself but didn’t get it?” The question was asked from all participants, irrespective of history of service use in the past year.

In addition, sex, age and race/ethnicity (non-Hispanic White, non-Hispanic Black, Hispanic, other) were assessed in all three surveys and included in the regression analyses.

**Analytic approach**
Trends over the 2001-2012 period were assessed using binary logistic regression models. Survey year was the independent variable of interest in these analyses and was recoded to range from 0 (for 2001-2002) to 1 (for 2011-2012). Thus, the odds ratios associated with the variable of survey year reflect the change in odds over the entire 2001-2012 period. Survey years were combined in 2-year bins to increase stability of estimates. For assessment of trends in major depressive episodes, only years 2005-2012 were included in the analyses and the survey year variable was accordingly coded to range from 0 to 1 for this time period. Both unadjusted and adjusted regression analyses were conducted for each outcome. The adjusted models controlled for sex, age and race/ethnicity to remove the potential effect of variations in these characteristics of the samples over time.

Analyses were weighted by survey weights which make the samples representative of the target population. All percentages reported are weighted by these survey weights. Analyses further adjusted for survey design elements using Taylor linearization method as implemented in the STATA 13 (StataCorp LP, College Station, TX) complex survey commands. Due to the large sample sizes, conservative 99% confidence intervals and p<.01 were used.

RESULTS

Psychological distress

A total of 54,985 (15.1%) of the 349,852 NHIS participants with K6 ratings scored in the ≥5 to <13 range indicating moderate psychological distress. Another 12,207 (3.1%) scored in the ≥13 range indicating severe psychological distress. In unadjusted logistic regression analyses, no significant trends were observed over time (odds ratio [OR]=1.02, 99% CI=.97-1.07, p=.253 for moderate distress and OR=1.05, 99% CI=.96-1.15, p=.161 for severe distress). The results were similar in adjusted models controlling for sex, age and race/ethnicity (Table 1).

Major depressive episodes
A total of 25,156 (7.0%) of the 301,577 NSDUH 2005-2012 participants met the criteria for a major depressive episode in the past year. The prevalence did not appreciably change over the 8 years in unadjusted analyses (OR=.98, 99% CI=.95-1.00, p=.072) or adjusted analyses (Table 1).

**Number of days with poor mental health**

Of the 4,229,051 BRFSS 2001-2012, a total of 323,061 (7.5%) reported poor mental health for at least half of the days in the past month and 226,991 (5.1%) reported poor mental health for the whole 30 day period. In unadjusted analyses, the odds of having ≥15 days of poor mental health increased by 24% over the 12-year period (OR= 1.24, 99% CI=1.20-1.28, p<.001) and the odds of having 30 days of poor mental health increased by 4% (OR= 1.04, 99% CI=1.02-1.05, p<.001) (the model for 30 days of poor mental health did not converge using survey weights and design elements; the model was estimated without these elements). The results were similar in models adjusted for age, sex and race/ethnicity (Table 1). The average number of days with poor mental health increased from 3.4 days in 2001-2002 to 3.9 days in 2011-2012 and the incidence of days with poor mental health increased modestly by about 15% as examined using a negative binomial regression model (incidence rate ratio= 1.15, 99% CI=1.13-1.17, p<.001) (data not shown).

**Taking prescription medication**

Of the 452,051 NSDUH 2001-2012 participants who responded to the question about taking prescription psychiatric medication, 47,205 (10.8%) responded positively. In unadjusted analyses, the odds of taking psychiatric medication increased by about 22% over the 12 years period (OR=1.22, 99% CI=1.16-1.28, p<.001). The statistically significant temporal trend persisted in adjusted analyses (Table 1).
Seeing mental health professionals

Of the 345,705 NHIS 2001-2012 participants who responded to the question about seeing a mental health professional in the past year, 25,277 (7.0%) responded positively. In unadjusted analyses, the odds of seeing a mental health professional increased by 33% over the 12-year period of the study (OR=1.33, 99% CI=1.25-1.41, p<.001). The statistically significant temporal trend persisted in the adjusted analyses (Table 1).

Any mental health treatment

Of the 451,409 NSDUH 2001-2012 participants who responded to questions about any form of treatment for mental health problems, 59,007 (13.1%) reported at least one type of service use. In unadjusted analyses, the odds of mental health treatment increased by 14% over the 12 year period (OR=1.14, 99% CI=1.07-1.21, p<.001). The statistically significant temporal trend persisted in analyses adjusted for age, sex and race/ethnicity (Table 1).

Perceived unmet need for mental health treatment

Of the 451,656 NSDUH 2001-2012 participants who responded to questions regarding perceived unmet need, 30,592 (4.9%) responded positively. The odds of perceived unmet need for treatment did not appreciably change over the years in unadjusted analyses (OR=1.00, 99% CI=.99-1.01, p=.937) or adjusted analyses (Table 1). Among participants who received any mental health care, the prevalence of perceived unmet need was 18.9% across survey years and did not change significantly over time (data not shown).

DISCUSSION

This study recorded modest increases in mental health treatment seeking and the use of psychiatric medications in the US in the first decade of this century. However, we observed few changes in the prevalence of severe or moderate psychological distress, assessed using the K6
measure, in prevalence of depressive symptoms meeting the threshold of a major depressive episode assessed using a structured interview or in perceived unmet need for mental health care. Indeed the global assessment of the number of days with poor mental health showed a very modest but consistent increase over time. These trends are consistent with those shown for the decade of 1990s which also showed evidence of even more rapid increases in the service use and little evidence of a reduction in the prevalence of mental disorders.1, 5, 9

The expectation to see a decrease in the prevalence of distress or depressive symptoms with increase in treatment seeking is not unjustified. Increase in the use of statins has led to significant reduction in population cholesterol levels.23 Similarly, growth in treatment of hypertension has led to better control of this illness.24 Yet, there is no clear evidence that expansion in the treatment of mental disorders or psychological distress has led to reduced prevalence or incidence of these conditions.

These results are open to a number of interpretations as discussed by us and other investigators.9, 10, 25 Secular trends in psychological distress and depression have been noted in the past26-29 and it is possible that the prevalence of psychological distress, depression and perceived unmet need for mental health care would have grown had they not been countered by the corresponding increases in prevalence of treatment. The first decade of the 21st century witnessed a number of social and economic developments in the US and other industrialized nations with potential implications for mental health of the affected populations. Most importantly, the financial crisis of 2008 was associated with significant drops in employment rates and financial assets. Evidence for negative effects of this crisis on mental health status of the population is growing.30-32

It is also possible that the public has become more comfortable discussing mental health issues and more willing to report psychological problems on surveys,33, 34 leading to an increase in the prevalence of self-reported psychological distress or depressive symptoms. Consistent with this view, a study comparing responses to three general population surveys in 1957, 1976
and 1996 found a significant increase in the percentage of US adults who reported an impending “nervous breakdown”—from 19% in 1957 to 26% in 1996.35

Another possible explanation for increase in service use in conjunction with no change in prevalence of psychological distress and depressive symptoms is that the available treatments may have been of low quality or intensity or not appropriately targeted. For example, the major growth in the use of antidepressant medications occurred in primary care settings and among patients with less severe mental health problems2, 14, 36 who may not respond to treatments to the same degree as patients with more severe problems.37 Poor targeting of treatments may result in attenuation of treatment effects. Disparities in access to mental health services have been repeatedly noted in past research.38-45 Data on the use of psychiatric medications further highlight poor targeting in some population subgroups.14 For example, while prevalence of depression and other common mental disorders is lower among older adults compared to younger or middle-aged adults,46 the prevalence of psychiatric medication use among older adults is not proportionally lower.47 Our finding of no change in prevalence of perceived unmet need is also consistent with poor targeting of services. If the additional service use was mainly limited to those whose needs were already met, it would not significantly impact the prevalence of unmet need for mental health care.

The discrepancy in the trends of psychological distress assessed using K6 which is comprised of specific questions about mood and anxiety and the trend in the global measure of poor mental health days is puzzling. It is possible that participants in more recent years reported their mental health as poorer when asked a general global question; whereas, in response to specific questions they did not appear to be more distressed in more recent years. It is also possible that the duration of mental health problems has increased in more recent years. However, an increase in duration should be reflected in prevalence of psychological distress as prevalence is influenced by both the incidence and duration.
The period covered in this study coincided with a number of Federal and state policy initiatives aimed at expanding access to mental health services that may have contributed to changes in accessibility of services.48-54 Most importantly, the enactment of the Mental Health Parity and Addiction Equity Act of 2008 required that insurance coverage of mental health and substance abuse services be equal to coverage of general medical and surgical care.52-54 At the state level, parity legislation and expansion of Medicaid programs have sought to expand access to mental health care.

It is not clear from the survey data reported here whether the modest changes in mental health treatment seeking reflect the effects of these trends. Future research need to explore whether these Federal and state policies had any appreciable impact on mental health service use.

With the full enactment of the Affordable Care Act (ACA) access to mental health services is likely to increase in the coming years. Judging from the trends in the past two decades, the mere expansion of services under ACA is not likely to result in a decrease in the prevalence of mental health problems. However, improved diagnosis and targeting of serious mental health conditions in primary care settings,47 enhancement of quality of available treatments,55 and greater emphasis on primary prevention of mental disorders9 or secondary prevention of recurrence of disorders25 may help improve the efficiency of the current treatments.

In interpreting these results, a number of limitations of this study should be considered. First, the mental health and service use measures used in this study were quite limited in scope. Prevalence of various mental disorders may have followed different trends. Second, the large sample sizes for these analyses meant that even modest changes over time in some measures were statistically significant. However, the odds ratios represent the magnitude of change and are not affected by sample size. In this regard, it is also noteworthy that small possible reductions in prevalence of psychological distress or mental disorders—which translate into
improvement in potentially millions of lives—may not be captured even in these large surveys. For example, the statistically non-significant 0.4% reduction in prevalence of major depressive episodes in the 2005-2012 period in NSDHU translates into approximately 1 million adults.

Larger population samples are needed to reliably assess changes of this magnitude. Third, psychological distress is known to impact service use and, in turn, may be impacted by service use. Due to the observational nature of the data these reciprocal influences cannot be separated in this study. Furthermore, it is not possible to assess whether the increase in psychiatric medication use is fully attributable to increased contact with mental health professionals since these estimates were based on different datasets. However, other studies have recorded an increase in prescription of psychiatric medications by general medical providers in recent years.56

In the context of these limitations, the data presented here provide a very broad picture of time trends in psychological distress and depressive symptoms in the US during the first decade of this century. We detected few changes in distress and depressive symptoms measured by objective rating scales or structured interviews. However, the study detected a modest increase in mental health service use, including medication use and contact with mental health professionals. The data presented in this report predate implementation of the major components of ACA, which will likely have a significant impact on delivery of mental health service. It would be important to continue monitoring the population’s mental health and service use status as the major components of this initiative are implemented in future years.

*Note: NHIS stands for National Health Interview Survey, BRFSS for Behavioral Risk Factor Surveillance System, and NSDUH for National Survey on Drug Use and Health.*

\(^a\)AOR stands for the adjusted odds ratios from logistic regression models and CI for confidence intervals around these AORs. Each AOR represents change in the odds of the outcome across the period of 2001 (or 2005 for major depressive episodes) to 2012, adjusted for sex, age and race/ethnicity of the participants.
