Kidney Regeneration Group, Murdoch Children's Research Institute

Submitted in total fulfilment of the requirements of the degree of
Doctor of Philosophy: Medicine, Dentistry and Health Sciences

Abstract

Genetic kidney diseases are a heterogeneous group of disorders with varying phenotypes dependent on the affected nephron segment. Next generation sequencing has increased our appreciation of the breadth of gene variants associated with these diseases. It has also identified large numbers of variants of unknown significance (VUS), which require functional genomic validation. There is an unmet need for novel therapies for genetic kidney diseases as most invariably progress to dialysis or transplantation without any form of targeted treatment.

Laboratory based research of genetic kidney disease requires the recapitulation of a disease phenotype in animal and/or *in vitro* cellular disease models. Interspecies variation in anatomy, physiology and gene function limits the translation of animal models to human disease and clinical care. Classical two dimensional cell cultures lack the complexity and intercellular cross-talk of *in vivo* three dimensional tissue. Kidney organoids are three dimensional, miniature, multicellular, human, *in vitro* micro-tissues, offering distinct disease modelling advantages over other models. Furthermore, kidney organoids can be regenerated from induced pluripotent stem cells (iPSC) reprogrammed from patients with genetic kidney disease, potentially providing outcomes with personalised clinical relevance. As a novel platform, the capabilities and limitations of kidney organoids as disease models are not well understood. By differentiating and characterising kidney organoids from the iPSC of patients with inherited kidney diseases, this thesis aims to explore the application of kidney organoids to disease modelling.

As proof of concept, kidney organoids were first generated from iPSC reprogrammed from a patient with compound heterozygous variants in *IFT140*, an already validated nephronophthisis (NPHP) genotype. An isogenic control was generated by precision CRISPR-Cas9 gene editing. In this project, differential primary ciliary morphology within organoid tubules and transcriptional profiling of organoid epithelium validated the ability of the organoids to model genetic disease.

Attempts were then made to validate novel, candidate variants for other pedigrees with unresolved trio whole exome sequencing. In a proband with clinically suspected NPHP, *DNAH5* was selected as a candidate gene, despite previously association with a motile ciliary phenotype. In this project, kidney organoids were unable to validate the patient

variant as pathogenic. In addition, a number of lessons were learned regarding the necessary variant curation process prior to making a commitment to modelling with kidney organoids.

In the final chapter, kidney organoids validated a novel genotype for the glomerular disease steroid resistant nephrotic syndrome, via international collaboration with the laboratory of Prof Friedhelm Hildebrandt. Glomeruli within kidney organoids differentiated from iPSC expressing a patient-derived, homozygous variant in *NOS1AP*, displayed aberrant development, increased podocyte apoptosis and reduced expression of PAR polarity proteins.

Together these projects demonstrate the strengths and challenges of using kidney organoids as models of inherited renal disease. Kidney organoids stand to complement animal and 2D unicellular disease models rather than replace them. We proposed that patient-derived kidney organoids are best placed to model paediatric onset kidney diseases with the future potential of providing personalised therapeutic screening.

Declaration

I declare this thesis comprises only my original work towards the Doctor of Philosophy except where indicated in the preface.

Due acknowledgement has been made in the text to all other material used.

The thesis is fewer than the maximum word limit in length, exclusive of tables, maps, bibliographies and appendices.

Signed: Dr Thomas A Forbes

Date:25 March 2020

Preface

Publication Status of Data Chapters and Contribution of Co-authors

Chapter 3: Published by American Journal of Human Genetics on 26th April 2018.

Dr Thomas Forbes led differentiation experiments, post-fixation analyses and wrote the manuscript. Dr Peter Trnka, Dr Chirag Patel and Assoc Prof Andrew Mallett recruited and phenotyped the patient. Assoc Prof Bruce Bennetts, Ms Gladys Ho, Ms Katherine Holman, Dr Cas Simons, Assoc Prof Andrew Mallett and Ms Joanna Crawford performed whole exome sequencing, analysis and Sanger sequencing of the patient-derived DNA. Dr Sara Howden generated and gene corrected iPSC clones. Dr Kynan Lawlor wrote post-immunofluorescent analysis scripts. Mr Sean Wilson assisted with protein assays. Dr Belinda Phipson and Dr Jovana Maksimovic assisted with bioinformatics analyses. Assoc Prof Alicia Oshlack supervised bioinformatics analyses. Prof Melissa Little, Assoc Prof Cathy Quinlan and Dr Lorna Hale supervised all experiments and manuscript revisions.

Chapter 4: Unpublished material not submitted for publication.

Dr Thomas Forbes led variant curation, differentiation experiments, HUREC cultures, post-fixation analyses and compiled all data. Dr Sara Howden generated and gene corrected iPSC clones. Dr Kynan Lawlor wrote post-immunofluorescent analysis scripts. Prof Melissa Little and Assoc Prof Cathy Quinlan supervised all experiments and manuscript revisions.

Chapter 5: Unpublished material submitted for publication.

Dr Thomas Forbes performed all differentiations, post-fixation analyses, wrote post-immunofluorescence analysis scripts and compiled all data. Dr Kynan Lawlor assisted with bioinformatics analysis. Ms Michelle Scurr assisted with sectioning and immunohistochemistry. Dr Friedhelm Hildebrandt, Dr Amar Majmundar and Dr Florian Buerger assisted with histology analysis. Prof Sara Ellis, Mr Cameron Skinner, Ms Judy Borg and Ms Hanadi Hoblos from the Centre for Advanced Histology and Microscopy, Peter McCallum Cancer Centre, Melbourne, prepared transmission electron microscopy grids and assisted with imaging. Ms Bronwyn

Christiansen, Department of Anatomical Pathology, Royal Children's Hospital, Melbourne, performed PAS stains. Prof Melissa Little supervised all experiments and manuscript revisions.

Funding Acknowledgements

I am grateful for the stipend support provided by the National Health and Medical Research Council Post Graduate Scholarship (GNT1114409) and RACP Jacquot NHMRC Award for Excellence administered by the Royal Australasian College of Physicians, the Australian and New Zealand Society of Nephrology and the Don and Lorraine Jacquot Estate.

Aspects of this thesis were funded by the National Health and Medical Research Council of Australia (NHMRC) (GNT1098654), Kidney Health Australia, the Royal Brisbane and Women's Hospital Foundation, the Royal Children's Hospital Foundation, and the Murdoch Children's Research Institute. The Murdoch Children's Research Institute is supported by the Victorian Government's Operational Infrastructure Support Program.

Acknowledgements

I wish to acknowledge the entire Kidney Development, Disease and Regeneration team, dynamic as it has been over the last 4 years. This includes (in no particular order): Minoru Takasato, Pei Er, Irene Ghobrial, Lorna Hale, Shahnaz Khan, Alex Combes, Sara Howden, Jess Vanslambrouck, Siebe Spijker, Alison Graham, Michelle Scurr, Louise Wardrop, Sean Wilson, Lakshi Starks, Joanne Soo, Pamela Karaith, Penny McDonald, Gemma Martinez, Ker Sin Tan, Santhosh Kumar, Aude Dorison, Andrew Mallett, Belinda Phipson, Alicia Oshlack, Andrew Lonsdale and Linda Cox. I walked into this PhD without having ever picked up a pipette. You have been tremendously patient with me as I learned the ropes, and supportive of my progression as a scientist. It means so much to me to be able to get out of bed in the morning with enthusiasm for the people I see and the work that I do. I am so excited for the opportunities we approach together in future. Within this group I highlight Kynan Lawlor, one of the most selfless, relaxed and highly efficient colleagues I've ever worked with in medicine or science. Kynan spent a great deal of time working with me to optimise some complex post-immunofluorescent analyses, many of which didn't work, but this never phased him. There remains so much for me to learn from him.

Outside of the Kidney Regeneration Group sincere thanks to the generosity of my MCRI colleagues and collaborators from other groups including Cas Simons, Sue White, Matt Burton, Eleanor Jones, Paul Lau, Maelle Le Moing, Stefanie Eggars, Peter Houweling, Chrystal Tiong and Jovana Maksimovic.

I am incredibly grateful to Prof Friedhelm Hildebrandt for the opportunity to collaborate on the *NOSIAP* project. When I first started my PhD I read so much of his work I recall joking to my colleagues about how impossibly but incredibly prestigious it would be to work with him. Thank you also to Amar Majmundar and Florian Buerger for their assistance with this project. To have been welcomed so warmly into this cooperative and industrious group of collaborators is my privilege.

Thank you to all my clinical colleagues for their support and understanding over the last four years of frequent distraction and obsession with this PhD.

Thank you to my Thesis Advisory Committee Shireen Lamande, David Elliot and Joshua Kausman who provided regular boosts of support and endorsement along the way.

My supervisors Prof Melissa Little and Assoc Prof Cathy Quinlan have been a constant source of empathy, support and encouragement throughout this process, including the many challenges that arose outside of the professional environment.

I'm so lucky and grateful to have the most wonderful family. Thank you to Mum, Dad, Lucy and Fergus, Marian and Kethly, and David and Liz for being so understanding, and tolerant of my ridiculous workload over the last four years and for all your interest, love and support over this time.

To my children Penny and Cate, I don't expect you'll ever read beyond this page but in the hope that one day you might at least read this paragraph, know that I love you both more than anything in the world. With quite genuine sincerity, I could not have endured the lows of this PhD without your cuddles and love, and I thought of you at every high. You are such considerate and smart kids. I am so proud of you, and will always be.

To my wife Beth. You know more than anyone how this career redirection has pushed me to (and sometimes beyond) my limit. I simply would not have completed this without you. Well beyond looking after the kids and managing our lives whilst I spent hours in the lab, ward and office, you have been and will continue to be my inspiration in work, love and life. I love that every challenge we face together brings us closer, and that we've never been wary of looking for the next challenge. Thank you for holding me together.

Chapter 1 Introduction

1.1 The health and economic burden of genetic kidney disease

The natural history of many, if not most, inherited kidney disease entails a slow but inexorable decline in kidney function towards end stage kidney disease (ESKD) and the eventual requirement of renal replacement therapy. Dialysis and transplantation are capable of extending the lives of these patients for many years, however this is usually with compromised health and quality of life. These treatments are also expensive with the estimated health service expenditure between \$AUD53,000 and \$AUD101,000 per patient per year of dialysis (AIHW, 2012) and approximately \$AUD110,000 per patient over the first three years following transplantation.(Cass A, 2010) The treatment of chronic kidney disease (CKD) is projected to consume 1.7% of total government health expenditure in Australia reflecting a cost of over \$12-13 billion annually by the year 2020.(AIHW, 2014)

Over the last decade, there has been a considerable expansion in the identification of genes responsible for CKD, spurred by advances in Next Generation Sequencing technology.(Renkema et al., 2014, Halbritter et al., 2013, Gee et al., 2014b, Mallett et al., 2017) Approximately 10-20% of adults and 47% of children with CKD in Australia have a genetic aetiology to their disease.(Mallett et al., 2014, Fletcher et al., 2013) There is

therefore a pressing need to improve the understanding of the pathogenesis of inherited kidney disease in order to develop targeted treatments that can reduce this morbidity and expenditure.

1.2 Induced pluripotent stem cells and kidney organoids

In 2007, the laboratory of Shinya Yamanaka published a protocol for the reprogramming of human skin fibroblasts into induced pluripotent stem cells (iPSC) using a straightforward viral vector transfection.(Takahashi et al., 2007) Under the right culture conditions, human iPSC are theoretically capable of differentiation to any cell type within the human body. As such, the discovery of iPSC has given rise to a new branch of science and medicine called *Regenerative Medicine*, whereby iPSC can be reprogrammed from patient-derived somatic cells and then differentiated to a target cell type or tissue of interest, providing a protocol is known.(Hariharan et al., 2015, Cherry and Daley, 2013, Singh et al., 2015)

An iPSC-derived, regenerated tissue which resembles the primary organ is called an *organoid*. The last decade has seen a wave of protocols published for the derivation of various organoids including but not limited to blood cells(Zhang, 2013, Yang et al., 2017, Sweeney et al., 2016), neurons(Lancaster et al., 2013), retina(Parfitt et al., 2016, Reichman et al., 2017), cardiomyocytes(Giacomelli et al., 2017) and hepatocytes(Hannan et al., 2013). Concurrently, about five years ago, multiple laboratories published protocols for the directed differentiation of iPSC to kidney organoid.(Morizane et al., 2015, Takasato et al., 2015, Mae et al., 2013, Taguchi et al., 2014, Lam et al., 2014b, Imberti et al., 2015) Almost all protocols use *in vitro* growth factors to recapitulate what is understood about *in vivo* kidney development from the study of animal models.

The long term aspiration of regenerative medicine involves the creation of patient-specific cells and tissues as transplantable therapies for the treatment of organ injury and failure. However, a more immediately translatable application of regenerated organoids is in disease modelling, which describes the *in vitro* culture of patient-iPSC-derived organoids to study the mechanisms of disease and to conduct personalised therapeutic screening.

Currently, targeted therapies to modify the primary mechanism of inherited kidney diseases are few and almost ubiquitously developed using non-human research models (eg. mouse, zebrafish, etc). The timely translation of these discoveries to human patients in a clinically relevant context is limited by interspecies variability in organ development, gene expression and physiological function. The extent to which these regenerated kidneys can faithfully reproduce a kidney disease *in vitro* is incompletely illustrated in the current literature and is likely to vary based on many factors including the disease mechanism, the age of onset, the genetic contribution to disease and the organoid's representation of the primary cell type affected by the disease. This thesis aims to examine the capabilities and limitations of kidney organoids as living, *in vitro* functional genomic models by examining kidney organoids differentiated from the iPSC of patients with genetic kidney diseases.

1.3 Hypothesis and Aims

This thesis will address the hypothesis that iPSC-derived kidney organoids represent a novel and valid disease modelling platform for inherited renal diseases and have the potential to validate novel genomic variants discovered by next generation sequencing and advance the understanding of disease pathogenesis. To this end, the aims of this thesis are:

- i. To demonstrate the ability of patient-iPSC-derived kidney organoids to faithfully model both glomerular and tubular inherited kidney diseases.
- ii. To characterise the disease phenotype of iPSC kidney organoids derived from a patient with a previously validated pathogenic genetic variant.
- iii. To validate the disease phenotype of a novel, candidate renal disease genotype in kidney organoids.

Chapter 2 Background

2.1 Preface

This chapter begins by providing a summary of the functional unit of the kidney: the nephron. The nephron is anatomically divided into segments with specific and differential functions determined by the cell types present within them.(Figure 2.1) An understanding of the nephron segments is important to comprehend the wide variety of disease phenotypes that can arise in genetic kidney disease.(Table 2.1) This understanding is also critical to be able to appraise the end product of iPSC-to-kidney differentiation protocols, the kidney organoid.

The projects presented in this thesis (Chapters 3-5) focus on two specific, paediatric, inherited kidney diseases: nephronophthisis (pronounced *nef – ron – of – thee – sis*, NPHP) and steroid resistant nephrotic syndrome (SRNS). Therefore a detailed discussion of the current clinical management and molecular understanding of both NPHP and SRNS is presented in Section 0 and 2.4.

This chapter then moves on to introduce kidney organoid differentiation protocols in Section 2.5. As these protocols are based heavily on our understanding of *in vivo* kidney development, a detailed description of mammalian kidney development is provided. The various published kidney organoid differentiation protocols are then compared and contrasted. Finally, examples of kidney organoids used for inherited disease modelling purposes is presented.

2.2 Inherited Kidney Disease

The functional unit of the kidney is the *nephron*. Normal mammalian kidney development gives rise to a pair of kidneys possessing a total of between 200,000 and 2.7 million nephrons.(Hoy et al., 2003, Hughson et al., 2003) The nephron is segmented into 6 major segments: the renal corpuscle, the proximal convoluted tubule (PCT), the descending limb of the loop of Henle (LoH), the ascending limb of the LoH, the distal convoluted tubule (DCT) and the collecting duct (CD). The appropriate distribution and function of a wide variety of cell types within sequential nephron segments results in the meticulous regulation of serum biochemistry, acid-base balance, total body water content, excretion of nitrogenous waste and hormonal responses. This section describes the function of each nephron segment from proximal to distal, and briefly summarises the genetic phenotype characteristic for diseases of each segment. An overview of the wide spectrum of inherited kidney diseases is presented in Table 2.1.

2.2.1 Glomerulus

Each nephron is perfused by an afferent arteriole which supplies the *glomerulus*, a bundle of fenestrated capillaries supported structurally by mesangial cells and covered by a visceral epithelial layer of *podocytes*.(Figure 2.1) Podocytes are highly specialised cells which anatomically interact via interdigitating foot processes bridged by slit diaphragms of specialised proteins, including nephrin, podocin and kirrel.(Reiser and Altintas, 2016, Grahammer et al., 2013) More than a simple proteinaceous sieve, the slit diaphragm is recognised to function as a specialised cell junction, capable of chemical and mechanosensory signalling to podocytes and thereby mediating cytoskeletal dynamics, and essential podocyte functions.(Grahammer et al., 2013) Together the podocytes and the glomerular endothelium produce a glomerular basement membrane (GBM) which sits between them, composed of type IV collagens, laminins and other matrix elements with

Figure 2.1 The nephron

A single nephron illustrating the complex anatomy and architecture of the different segments and cell types, and a description of their varied, specialised functions. GBM: glomerular basement membrane, AQP2: aquaporin 2, AVP: arginine vasopressin, EPO, erythropoietin. (Reprinted by permission from Springer Nature: Little MH et al, Recapitulating Development to Generate Kidney Organoids Culture In: Organ Regeneration Based on Developmental Biology, Ed. Takashi Springer, Singapore, Copyright 2017)

which both cell types interact for normal function.(Byron et al., 2014, Abrahamson, 2012) The endothelium, the GBM and podocyte slit diaphragm together form the glomerular filtration barrier.(Arif and Nihalani, 2013) Blood entering the glomerular capillaries is filtered by hydrostatic pressures through this barrier, retaining cells and high molecular weight proteins in the healthy state by virtue of size and negative charge selectivity of the barrier.(Fissell and Miner, 2018) This filtrate is collected by Bowman's capsule which is lined by flat, parietal epithelial cells(Shankland et al., 2014) and feeds the filtrate into a single, unidirectional tubule which passes the filtrate through multiple segments, processing the filtrate into urine.

Inherited disease involving the glomerulus can present with haematuria and/or proteinuria (Table 2.1) resulting from disruption of the glomerular filtration barrier and/or effacement of the podocyte foot processes. This can result from defects in the proteins making up the GBM (eg. Alport Syndrome), (Lemmink et al., 1994, Mochizuki et al., 1994) glomerular deposition of abnormal proteins (eg. Fibronectin glomerulopathy)(Castelletti et al., 2008) or defects in the homeostasis of the podocytes (eg. steroid resistant nephrotic syndrome)(Joshi et al., 2013, Lovric et al., 2016, Preston et al., 2019).(Table 2.1) Genetic forms of steroid resistant nephrotic syndrome (SRNS) represent the second most common cause of CKD in children.(Fletcher et al., 2013, 2014) A detailed discussion of SRNS is presented in Section 2.4. Additionally, inherited diseases of systemic complement regulation can lead to thrombotic micro-angiopathy within glomerular capillaries which can cause acute disturbances in the kidneys excretory function.(Aguilar, 2016)

2.2.2 Proximal Tubule

The PCT is lined by cuboidal epithelium possessing a long brush border to maximise the apical cell surface area interacting with the early glomerular filtrate (Figure 2.1) and which avidly binds *Lotus tetragonolobus* lectin (LTL).(Schulte and Spicer, 1983, Hennigar et al., 1985) The role of the PCT is to reabsorb (or reclaim) the bulk of solutes and water from the early glomerular filtrate. This includes 30-50% of filtered potassium, 60-70% of filtered water, sodium, chloride and bicarbonate and 90-100% of filtered glucose, amino acids, low molecular weight protein and phosphate.(Curthoys and Moe, 2014) This is enabled by the establishment of a sodium concentration gradient established by basolateral expression of Na-K-ATPase pump and a series of apical Na-cotransporters

which exploit this gradient.(Curthoys and Moe, 2014) Water absorption occurs through aquaporin 1(AQP1). Limited protein reabsorption from the urinary filtrate occurs via endocytosis after binding to megalin and cubulin proteins expressed on the luminal surface of PCT cells.(Nielsen et al., 2016)

A critical function of the PCT is the stringent maintenance of acid-base balance. In response to acidosis, the PCT maximises its bicarbonate reabsorption and increases its glutamine uptake to metabolise α -ketoglutarate and ammonia.(Hamm et al., 2015) The former can be metabolised by the liver to regenerate bicarbonate and the latter increases acid secretion from intercalated cells in the DCT/CD.(Hamm et al., 2015)

As a consequence of its high re-absorptive capacity and metabolic activity, the PCT is exposed to high levels of filtered drugs and is the major site of nephron injury due to nephrotoxic agents.(Soo et al., 2018) PCT cells also play key endocrine roles in homeostasis, for example, erythropoietin production, activation of vitamin D precursors, production of renin.(Lacombe et al., 1991, Nykjaer et al., 1999, Moe et al., 1993)

Inherited diseases of the PCT may either present as a specific transport defect or a global failure of the reabsorptive capacity of the PCT, eponymously labelled *Renal Fanconi syndrome*. Renal Fanconi syndrome is recognised by the presence of glucose, low molecular weight protein and excess sodium, potassium, phosphate, and other electrolytes in a dilute urine. Table 2.1

2.2.3 *Loop of Henle*

The LoH extends from the PCT down into the medulla, performing a hairpin turn before ascending to transition into the DCT.(Figure 2.1) It contains three segments, the thin descending limb, the thin ascending limb and the thick ascending limb. The descending limb is highly permeable to water and impermeable to solutes. Therefore, as the loop descends into the hyperosmolar medullary interstitium, the urinary filtrate becomes hyperosmolar.(Hall, 2016, Kokko, 1970) In contrast, the ascending limb is impermeable to water but relatively permeable to ions, which passively diffuse across the squamous membrane down a concentration gradient.(Hall, 2016)

In the thick ascending limb, as in the PCT, active solute transport is driven by a basolateral Na/K/ATPase pump which drives sodium out of the cell and potassium into the cell creating concentration gradients for both across the apical membrane.(Greger, 1985) NKCC2 symporters (gene *SLC12A1*) utilise these gradients to reabsorb 20% of filtered solute in this segment. A basolateral chloride channel Cl-CKb (gene *CLCKNB*) allows systemic chloride reabsorption across the basolateral membrane and critically requires the Barttin subunit (gene *BSND*) for its function.(Estevez et al., 2001) A positive electrochemical gradient is created in the tubular lumen by apical potassium escape from epithelial cells through the ROMK channel (gene *KCNJ1*). This gradient drives paracellular reabsorption of divalent cations (Ca^{2+} and Mg^{2+}) via the Claudin 16 paracellular channel.(Greger, 1985)

Together the differing permeabilities of the descending and ascending limbs of the LoH generate a countercurrent multiplier system which creates an osmolality gradient within the renal interstitium which is highest in the medulla.(Sands and Layton, 2009, de Rouffignac, 1972) This is maintained by blood flow through the *vasa recta*, a capillary network which is a direct extension of the efferent glomerular arteriole for the same glomerulus. This maintenance of a hyperosmolar medullary interstitium is critical to the function of aquaporin channels in the medullary CD, which permit passive water reabsorption across an osmolar gradient during periods of dehydration.

The dominant disease phenotype of the LoH is Bartter Syndrome which represents a failure of the powerful sodium reabsorption mechanism in the thick ascending limb. Multiple dyselectrolytaemias develop due to the reliance of many secondary electrolyte reabsorption mechanisms on this inward sodium current. Bartter Syndrome can present antenatally with polyhydramnios or postnatally with failure to thrive, polyuria and urinary salt wasting.(Table 2.1)

2.2.4 *Distal Convuluted Tubule and Collecting Duct*

The DCT receives a relatively dilute filtrate following the active solute reabsorption in the preceding tubular segments. The early part of the DCT makes contact with the glomerulus from the same nephron to form the juxtaglomerular apparatus (JGA).(Guyton et al., 1964, Perlewitz et al., 2012) Cells of the JGA sense the composition of the filtrate

and feedback via control on glomerular filtration pressure.(Perlewitz et al., 2012)(Figure 2.1) For example, in response to high filtrate osmolality (reflecting a dehydrated state) the JGA secretes renin, which stimulates a cascade of arteriolar vasoconstrictors (angiotensin I & angiotensin II).(Friis et al., 2013, Thatcher, 2017) This increases systemic vasomotor tone to maintain tissue perfusion and decreases renal blood flow whilst maintaining GFR until such time as the low circulating volume falls below a threshold for adequate renal blood flow, at which point kidney function declines.(Thatcher, 2017) The DCT is impermeable to water and participates in active ion solute reabsorption, increasingly diluting the urinary filtrate before its entry into the CD.(Hall, 2016) The thiazide sensitive, apical NCCT symporter (gene *SLC12A3*) transports sodium and chloride into the DCT epithelial cell which is moved across the basolateral membrane by chloride channel CLCNKB and the Na-K-ATPase pump. Magnesium and calcium reabsorption in this segment is passive across the apical membrane (TRPM6 and TRPV5 respectively) and by sodium exchange across the basolateral membrane (unknown and NCX respectively).

The DCT and CD both contain *principal* and *intercalated epithelial cells*.(Chen et al., 2017)(Figure 2.1) Principal cells express ENaC and ROMK which reabsorb sodium and secrete potassium respectively in response to aldosterone.(Pearce et al., 2015, Pearce et al., 2016) Additionally, principal cells regulate serum osmolality by the movement of aquaporin 2 channels into and out of the apical membrane in response to arginine vasopressin (AVP).(Pearce et al., 2015, Pearce et al., 2016) AVP is released by the posterior pituitary in response to increased serum osmolality which is detected by osmoreceptors in the hypothalamus. The effect of AVP binding to the principle cell receptors is to insert aquaporin 2 (AQP2) channels into the apical membrane, permitting increased free water movement by osmosis, from the relatively hypo-osmolar urinary filtrate to the relatively hyperosmolar medullary interstitium. These processes are critical to the maintenance of sodium and water balance, and thus systemic blood pressure. Once thought to play a focal role in maintenance of acid base balance with a high capacity for secretion of hydrogen ions, recent characterisation of intercalated cells has revealed three intercalated cell types with a broader repertoire of metabolic functions.(Rao et al., 2019, Roy et al., 2015) These cells display differential apicobasal expression of H⁺-ATPase, Pendrin and *SLC4A9*, display transdifferentiation between subtypes and perform

Disease Name	Inheritance	Genes	Phenotype	OMIM Phenotype Ref
Glomerular Disease				
Steroid Resistant Nephrotic Syndrome	See (Table 2.4), includes syndromic SRNS.			
Alport Syndrome/Thin GBM Membrane Nephropathy	XL, AR, AD	<i>COL4A5, COL4A3, COL4A4, MYH9</i>	Recurrent visible haematuria, proteinuria, sensorineural hearing loss, retinal flecks, ESRD.	301050, 203780, 615573, 153640
Fabry's Disease	XL	<i>GLA</i>	Proteinuria, neuropathy, neuropathic pain, acroparasthesias, cardiomyopathy, cardiac ischaemia, arrhythmia, hyperhidrosis, angiokeratomas, cerebrovascular disease.	301500
Fibronectin Glomerulopathy	AD	<i>FNI</i>	Glomerular deposit disease: haemoproteinuria, renal tubular acidosis, ESRD	135600
Thrombotic thrombocytopenic purpura	AR	<i>ADAMTS13</i>	Fever, thrombocytopenia, anaemia, neurological deficits, seizures, acute kidney injury.	604134
Atypical haemolytic uraemic syndrome (aHUS)	AR, AD	<i>C3, CD46, CFB, CFH, CFHR1, CFHR3, CFHR4, CFI, DGKE, THBD</i>	Haemolytic anaemia, thrombocytopenia, acute kidney injury, haemoproteinuria, ESRD.	235400, 612922, 612923, 612924, 612925, 612926, 615008
Familial amyloidosis	AD	<i>FGA, LYZ, APOA1, B2M</i>	Haemoproteinuria, hypertension, hepatosplenomegaly, glaucoma, polyneuropathy, variable extra-renal amyloidosis, ESRD.	105200
Proximal Tubule				
Renal glycosuria	AD	<i>SLC5A2</i>	Benign glycosuria with normoglycaemia	233100
Hereditary renal hyperuricaemia	AR	<i>SLC22A1, SLC2A9</i>	Uric acid nephrolithiasis, exercise induced acute kidney injury.	220150, 612076
Cystinuria	AR, AD	<i>CLD3A1, SLC7A9</i>	Increased urine cystine, recurrent cystine nephrolithiasis.	220100
Proximal renal tubular acidosis	AR	<i>SLC4A4</i>	Acidosis, hypokalaemia, metabolic bone disease from chronic acidosis.	604278
Dicarboxylic aminoaciduria	AR	<i>SLC1A1</i>	Asymptomatic, elevated urine aspartate, ketotic hypoglycaemia, nephrolithiasis, neurological/developmental anomalies.	222730
Hypophosphataemic Rickets	XL, AR, AD	<i>PHEX, FGF23, ENPP1, DMP1</i>	Hyperphosphaturia, growth delay, osteomalacia, rickets, fractures, nephrocalcinosis.	307800, 193100, 613312, 241521
Fanconi-Bickel Syndrome	AR	<i>SLC2A2</i>	Glycogen storage disease type XI, renal Fanconi syndrome.	227810
Primary renal Fanconi Syndrome Type 1-4	AD, AR	<i>GATM, SLC34A1, EHHADH, HNF4A</i>	Renal Fanconi Syndrome (HNF4A: neonatal hyperinsulinaemia, macrosomia, maturity onset diabetes in the young – MODY)	134600, 613388, 616026

Disease Name	Inheritance	Genes	Phenotype	OMIM Phenotype Ref
Lowe Syndrome	XL	<i>OCRL</i>	Renal Fanconi Syndrome	309000
Dent's Disease	XL	<i>CLCN5, OCRL</i>	Low molecular weight proteinuria, nephrocalcinosis, progressive CKD.	300009, 300555
Nephropathic Cystinuria	AR	<i>CTNS</i>	Renal Fanconi Syndrome, ocular crystals, growth impairment, hypergonadotrophic hypogonadism, weakness, hypohydrosis, hypothyroidism, neurological problems.	219800
Isolated Proteinuria	AR	<i>CUBN</i>	Isolated benign proteinuria, megaloblastic anaemia (Vit B12 deficiency).	261100
Loop of Henle				
Bartter Syndrome	AR	<i>SLC12A1, KCNJ1, CLCNKA, CLCNKB, BSND</i>	Hyponatraemia, hypokalaemia, metabolic alkalosis, hypocalcaemia, hypomagnesaemia, polyuria, failure to thrive, arrhythmia.	601678, 241200, 607364, 613090, 602522
Distal Tubule				
Gitelman Syndrome	AR	<i>SLC12A3, CLCNKB</i>	Hypokalaemia, hypomagnesaemia, metabolic alkalosis, salt craving, arrhythmia.	263800
Hereditary hypomagnesaemia	AR	<i>TRPM6, CLDN16, EGF, CLDN19</i>	Hypomagnesaemia, variable hypocalcaemia, hypercalciuria, myokymia/hypokalaemia.	602014, 248250, 611718, 248190
	AD	<i>FXYD2, CNNM2, KCNA1</i>		154020, 613882, 160120
Familial hypocalciuric hypercalcaemia	AR/AD	<i>CASR</i>	Hypocalciuria, hypercalcaemia, hyper/hypomagnesaemia, chondrocalcinosis, pancreatitis.	601199
Gordon Syndrome	AD	<i>WNK1, WNK4, KLHL3, CUL3</i>	Pseudohypoaldosteronism hypertension, hyperkalaemia, acidosis.	614491, 614492, 614495, 614496
EAST (SeSAME) Syndrome	AR	<i>KCNJ10</i>	Seizures, sensorineural hearing loss, ataxia, intellectual disability, hypokalaemia, alkalosis, hyponatraemia, hypomagnesaemia.	612780
ADTKD-UMOD	AD	<i>UMOD</i>	Bland urine sediment, hyperuricaemia, hypouricosuria, gout, medullary echogenicity, CKD, ESRD.	174000
ADTKD-REN	AD	<i>REN</i>	Childhood onset EPO-responsive anaemia, hyperuricaemia, gout, hypotension, CKD, ESRD.	613092
ADTKD-MUC1	AD	<i>MUC1</i>	Adult onset CKD between 30-60 years. Bland urine sediment. Medullary cyst kidney disease.	174000

Disease Name	Inheritance	Genes	Phenotype	OMIM Phenotype Ref
Collecting Duct				
Liddle Syndrome	AD	<i>SCNNIG, SCNNIB</i>	Salt sensitive hypertension, hypokalaemia, metabolic alkalosis, low renin and aldosteronism.	177200
Distal renal tubular acidosis	AR, AD	<i>ATP0A4;</i> <i>SLC4A1, ATPV1B1</i>	Isolated distal renal tubular acidosis, +/- haemolytic anaemia or progressive sensorineural hearing loss, nephrocalcinosis.	602722, 611590, 267300
Pseudohypoaldosteronism Type 1	AR	<i>SCNNIA,</i> <i>SCNNIG, SCNNIB</i>	Salt wasting, hyperkalaemia, acidosis, high aldosterone levels.	177735, 264350
Nephrogenic Diabetes Insipidus	XL, AD, AR	<i>AVPR2, AQP2</i>	Profound polyuria, polydipsia and hypernatraemia.	304800, 125800
Nephrogenic SIADH	XL	<i>AVPR2</i>	Hyponatraemia, hypo-osmolality, free-water excess.	300539
Pantubular/Non-Segment Specific				
ADPKD	AD	<i>PKD1, PKD2</i> <i>DNAJB11</i>	Adult onset ESRD, mitral valve prolapse, intracranial aneurysm and subarachnoid haemorrhage, hypertension, hepatic cysts.	173900, 613095, 618061
ARPKD	AR	<i>PKHD1, DZIP1L</i>	Fusiform dilation of collecting ducts causing antenatal to adult ESRD. Pulmonary hypoplasia. Hypertension. Biliary ductal plate malformation, congenital hepatic fibrosis, recurrent cholangitis.	263200, 617610
Nephronophthisis and related ciliopathies	See Table 2.2 and Figure 2.2.			
Congenital Abnormalities of the Kidney and Urinary Tract (CAKUT)				
Renal Cysts and Diabetes Syndrome	AD	<i>HNF1B</i>	Varied renal phenotype, bicornate uterus, hypomagnesaemia, gout, maturity onset diabetes in the young (MODY).	137920
Renal hypoplasia or aplasia	AR	<i>RET, PAX2,</i> <i>UPK3A, GRIB1L,</i> <i>ITGA8, FGF20,</i>	Highly variable from antenatal oliguria and Potter's sequence to benign, non-syndromic single kidney.	191830, 615721, 617805
Renal coloboma syndrome	AD	<i>PAX2</i>	Renal hypodysplasia, vesicoureteric reflux, colobomas.	120330
Branchio-oto-renal syndrome	AD	<i>EYAI, SIX1, SIX5</i>	Renal hypodysplasia, ear anomalies and sensorineural hearing loss, branchial fistulae.	113650, 610896
Hypoparathyroidism, deafness and renal disease syndrome.	AD	<i>GATA3</i>	Renal hypo/dysplasia, sensorineural hearing loss, hypoparathyroidism.	146255

Disease Name	Inheritance	Genes	Phenotype	OMIM Phenotype Ref
Kallmann syndrome	XL, AR	<i>KAL1, FGFR1</i>	Hypogonadotrophic hypogonadism, anosmia, cleft palate, sensorineural hearing loss, renal agenesis.	308700, 147950
Non-syndromic CAKUT	AD	<i>ROBO2, SOX17, TNXB, KMT2D, ETV4, SALL1, TBX18, DSTYK</i>	VUR, UPJO, VUJO, variable.	610878, 613674, 143400, 610805
Fraser Syndrome	AR	<i>FRAS1, FREM2</i>	Crypophthalmos, syndactyly, CAKUT, ambiguous genitalia, laryngeal/tracheal abnormalities.	219000
16p11.2 Deletion Syndrome	AD	<i>TBX6</i>	Central nervous system anomalies, autism, obesity, head and neck anomalies, growth defects, limb defects, kidney agenesis, VUR.	611913
Trichorhinophalangeal syndrome	AD	<i>TRPS1</i>	Sparse scalp hair, bulbous nasal tip, long flat philtrum, thin upper vermilion border, protruding ears, skeletal abnormalities, cone shaped phalangeal epiphyses, hip malformations.	190350
Multicystic Dysplastic Kidney	AD	<i>SRGAPI, NRIP1</i>	Ureterocele, Horseshoe kidney.	618270
Urofacial Syndrome	AR	<i>HPSE2</i>	Dysmorphic bladders, hydroureteronephrosis, VUR, hypertension, ESRD	236730
Simpson-Golabi-Behmel syndrome	XL	<i>GPC3, OFD1</i>	Gigantism, enlarged dysplastic kidneys	312870
Townes Brock syndrome	AD	<i>SALL1</i>	Imperforate anus, dysplastic ears, thumb malformations, hearing loss, congenital heart disease, CAKUT.	107480

Table 2.1 Monogenic causes of kidney disease

AD – autosomal dominant, AR – autosomal recessive, ADPKD, autosomal dominant polycystic kidney disease, ARPKD, autosomal recessive polycystic kidney disease, ADTKD – autosomal dominant polycystic kidney disease, CKD – chronic kidney disease, EAST – Epilepsy, Ataxia, sensorineural hearing loss and tubulopathy, ESRD – end-stage renal disease, GBM – glomerular basement membrane, XL – X linked, CAKUT – congenital abnormality of the kidney and urinary tract, VUR, vesicoureteric reflux, UPJO – ureteropelvic junction obstruction, VUJO – vesicoureteric junction obstruction. Adapted and updated from (Devuyst et al., 2014, van der Ven et al., 2018)

functions including acid secretion, bicarbonate secretion, regulation of sodium, chloride, potassium and calcium handling and most recently a role in the innate immune system of the collecting duct.(Rao et al., 2019, Roy et al., 2015)

Inherited disorders of the DCT/CD reflect the gain or loss of function of salt or acid handling transporters or regulators.(Table 2.1) Gitelman syndrome is the classical salt wasting phenotype for the DCT, classically presenting with hypokalaemia and hypomagnesaemia.(Riveira-Munoz et al., 2007, De Jong et al., 2002, Sabath et al., 2004) Disturbances in free water balance can result from gain or loss of function of AQP2 channels. Other rarer presentations are characterised by hypertension or salt wasting, potassium and acid-base disturbances given this segment is the terminal target of the renin-angiotensin-aldosterone axis.(Gordon, 1986, Pujo et al., 2007, Chang et al., 1996, O'Shaughnessy, 2015) Autosomal recessive polycystic kidney disease (ARPKD) is characterised by fusiform dilation of the collecting ducts and not infrequently presents with neonatal oligo-anuria and pulmonary hypoplasia with a high mortality, but can also present with a milder phenotype later in life.

2.2.5 Non-Segment Specific Inherited Kidney Disease

A number of genetic kidney disorders produce non-segment specific disease.(Table 2.1) For example, autosomal dominant polycystic kidney disease (ADPKD) is the most common, lethal monogenic worldwide with estimated incidence of between 1 in 500-1000.(Iglesias et al., 1983, Mallett et al., 2014, Baert, 1978, Lu et al., 1999) Both major gene products responsible for ADPKD (PKD1 and PKD2) localise to the primary cilium and are therefore labelled 'ciliopathies'. Since the discovery of the link between the primary cilium and polycystic kidney disease, NPHP has been established as another ciliopathy with a large and heterogeneous range of genetic variants and distinct syndromic associations. NPHP is one of the diseases modelled in this thesis and is discussed in detail in the next section. Other monogenic diseases can pre-dispose to metabolic crystal formation within the kidney leading to nephrolithiasis or nephrocalcinosis.(Devuyst et al., 2014, Daga et al., 2018)

Congenital abnormalities of the kidney and urinary tract (CAKUT) represent the most common cause of CKD in children.(Vivante and Hildebrandt, 2016, Fletcher et al., 2013)

This includes multicystic dysplastic kidney, renal agenesis, renal hypodysplasia, horseshoe kidney, duplex kidney and obstructive uropathies such as posterior urethral valves and pelviurethral junction obstruction, among others.(Verbitsky et al., 2019, van der Ven et al., 2018)

Whilst the representation of CAKUT in paediatric CKD is so high, one of the largest whole exome sequencing studies identified a monogenic cause in only 14% of pedigrees, although the unsolved rates were much lower in syndromic and reportedly consanguineous families. However, monogenic phenotype associations are far more variable than for other forms of inherited kidney disease, even within individuals of the same family with the same primary genomic variants. Further research has examined a more substantial database of almost 3000 patients and over 22,000 control subjects, establishing the role of large copy number variations in CAKUT.(Verbitsky et al., 2019)

Now that the general structure, function and genetic disease spectrum of the nephron have been summarised, this chapter will discuss the genetic and molecular basis underpinning NPHP and SRNS in more detail. NPHP is a progressive, fibrocystic, renal tubular ciliopathy which represents one of most common causes of end-stage renal disease in the first three decades of life.(Hildebrandt, 2016, Hildebrandt et al., 2011, Wolf, 2015) SRNS is the second most common cause of progressive CKD in children.(Fletcher et al., 2013, 2014) Both NPHP and SRNS almost invariably progress to ESRD and no targeted therapies exist to mitigate this outcome. Thus, there is an unmet need for novel disease modelling approaches for these diseases.

2.3 Nephronophthisis

NPHP is an autosomal recessive genetic renal disease and a common cause of ESRD in children and young adults.(Hildebrandt and Zhou, 2007) The word nephronophthisis is derived from the Greek words *nephros* meaning ‘kidney’ and *phthisis* meaning ‘wasting’. Patients with NPHP are phenotypically classified according the age at which they progress to ESRD. The most common type is juvenile NPHP which progresses to ESRD by a median age of 13 years.(Hildebrandt et al., 1992) Infantile NPHP has a median ESRD onset at 1 year of age (Gagnadoux et al., 1989), and adolescent NPHP 19 years of age.(Omran et al., 2000a) NPHP initially presents with symptoms of tubular dysfunction,

including growth failure, polyuria, polydipsia and secondary nocturnal enuresis due to impaired urinary concentrating ability. Symptoms and complications of CKD follow.(Hildebrandt and Zhou, 2007) Renal ultrasound may show normal or reduced kidney size and generally demonstrates increased echogenicity, reduced corticomedullary differentiation and variable cyst development.(Vester et al., 2010)

NPHP can present as an isolated disorder of the kidneys or, in 10-20% of cases, as part of a multisystem disease known as a ciliopathy (or nephronophthisis related ciliopathy syndrome – NPNP-RC).(Braun and Hildebrandt, 2016) Eponymous syndromes have been classified according to the spectrum of organ involvement however the sheer volume of genes discovered and the phenotypic variability observed within these syndromes is rendering these eponyms somewhat redundant. New phenotypes are also being described for known genes.(Devlin and Sayer, 2019)

Retinal disease is a common association with ciliopathies occurring in around 10-15% of cases (Wolf, 2015, Hildebrandt, 2016) because the light-sensing outer-segment of the retinal photoreceptor is connected to the main body of the cell by a primary cilium and relies on this cilium for the delivery of rhodopsins for vision.(Nemet et al., 2015, Taub and Liu, 2016) Considerable genetic and phenotypic variability occurs within these clinical syndromes. All NPHP-RC syndromes can variably include NPHP in their phenotypic spectrum. Meckel Gruber syndrome shares a number of genes with other syndromic ciliopathies and likely reflects the most severe end of the phenotypic spectrum associated with truncating variants, whilst hypomorphic alleles of the same genes present with milder phenotypes.(Hildebrandt et al., 2011)

On renal biopsy NPHP is histologically characterised by (i) tubular dilatation and atrophy, (ii) thickening, thinning and disintegration of the tubular basement membrane, (iii) tubulointerstitial and periglomerular fibrosis with or without a lymphocytic cellular infiltrate and (iv) the development of *ex vacuo* cysts.(Waldherr et al., 1982) Despite often being classified as a cystic kidney disease, the development of cysts in NPHP is variable in both timing and anatomical location within the kidneys.(Hildebrandt et al., 1992, Slaats et al., 2016) The renal medulla and corticomedullary junction is the classical site of cyst development but many patients will not develop cysts at all. Cyst often develop late in

Eponymous Syndrome	Phenotype (Major Features)	Genes Described
Senior Løken Syndrome (OMIM 266900)	<i>NPHP, retinitis pigmentosa, hepatic fibrosis</i>	<i>NPHP1, NPHP4, IQCB1, CEP290, SDCCAG8, WDR19, TRAF3IP1</i>
Cogan Syndrome (OMIM 257550)	<i>NPHP, oculomotor apraxia</i>	<i>NPHP1</i>
Mainzer-Saldino Syndrome (OMIM 266920)	<i>NPHP, retinitis pigmentosa, cone shaped pharyngeal epiphyses, flattened femoral epiphyses, hepatic fibrosis, short ribs, small thorax, short stature, broad femoral neck, postaxial polydactyly</i>	<i>IFT140</i>
Jeune Asphyxiating Thoracic Dystrophy (OMIM 208500)	<i>NPHP, short ribs, small thorax, pulmonary hypoplasia, respiratory insufficiency, short limbs, liver and pancreatic cysts, retinitis pigmentosa, postaxial polydactyly</i>	<i>15q13, IFT80, DYNC2H1, TTC21B, IFT144, NEK1, IFT121, WDR60, IFT140, IFT172, WDR34, CEP120, KIAA0586, DYNC2L1I, IFT52, TCTEX1D2, IFT43, IFT81, INTU, IFT27</i>
Cranioectodermal Dysplasia (OMIM 218330)	<i>NPHP, short ribs, small thorax, pulmonary hypoplasia, polydactyly, brachydactyly, hepatic fibrosis, dolichocephaly, facial dysmorphism, microdontia, nail dysplasia, retinitis pigmentosa</i>	<i>IFT122, IFT121, IFT43, IFT14F</i>
Oral-facial-digital Syndrome (OMIM 311200)	<i>Cleft lip, abnormal dentition, facial dysmorphisms, polydactyly, brachydactyly, cystic renal dysplasia, retinitis pigmentosa, congenital heart disease</i>	<i>OFD1, DDX59, SCLT1, C2CD3, TMEM231, TCTN3, C5ORF42, OFIP, NPHP1</i>
Joubert Syndrome (OMIM 213300)	<i>NPHP, retinitis pigmentosa, hypoplasia of the cerebellar vermis (molar tooth sign) intellectual disability, ataxia, oculomotor apraxia, occipito meningocele, meningomyelocele</i>	<i>>60 genes associated including, but not limited to: INPP5E, TMEM216, AHI1, NPHP1, CEP290, TMEM67, RPKGRIPL, ARL13B, CC2D2A, OFD1, TTC21B, TCTN1, TMEM237, TCTN3, ZNF423, KIF7, ARL3</i>
Alström Syndrome (OMIM 203800)	<i>NPHP, CAKUT, retinitis pigmentosa, sensorineural hearing loss, hepatic fibrosis, dilated cardiomyopathy, obesity, type 2 diabetes</i>	<i>ALMS1</i>
Bardet Biedl Syndrome (OMIM 209900)	<i>Cystic renal dysplasia, retinitis pigmentosa, intellectual disability, polydactyly, brachydactyly, obesity, congenital heart disease, liver fibrosis, hypogonadism, sensorineural hearing loss</i>	<i>BBS1, BBS2, ARL6, BBS4, BBS5, MKKS, BBS6, TTC8, PTHB1, BBS10, TRIM32, BBS12, MKS1, WDPCP, LZTFL1, IFT27, NPHP6, CEP19</i>
Meckel Gruber Syndrome (OMIM 249000)	<i>Posterior encephalocele, polydactyly, cystic kidney dysplasia, hepatic fibrosis, pre-axial polydactyly, Dandy-Walker malformation, cardiac malformations,</i>	<i>MKS1, TMEM216, TMEM67, CEP290, RPKGRIPL, CC2D2A, NPHP3, TCTN2, B9D1 B9D2, KIF14, TMEM107, CEP55, TXNDC15</i>

Table 2.2 Ciliopathy syndromes

This tables summarises the key features associated with NPHP-RC syndromes and the genes that are associated with them. Major features are presented in italic font but inter-individual phenotypic variability is high between subjects. Note that some genes are associated with multiple syndromes indicating a continuum of allelic severity (eg. *CEP290* in all of Senior Løken Syndrome, Joubert Syndrome and the most fulminant phenotype Meckel Gruber Syndrome). OMIM numbers are listed for the first described genotype for each phenotype. (adapted from (Braun and Hildebrandt, 2016, Devlin and Sayer, 2019, Wolf, 2015))

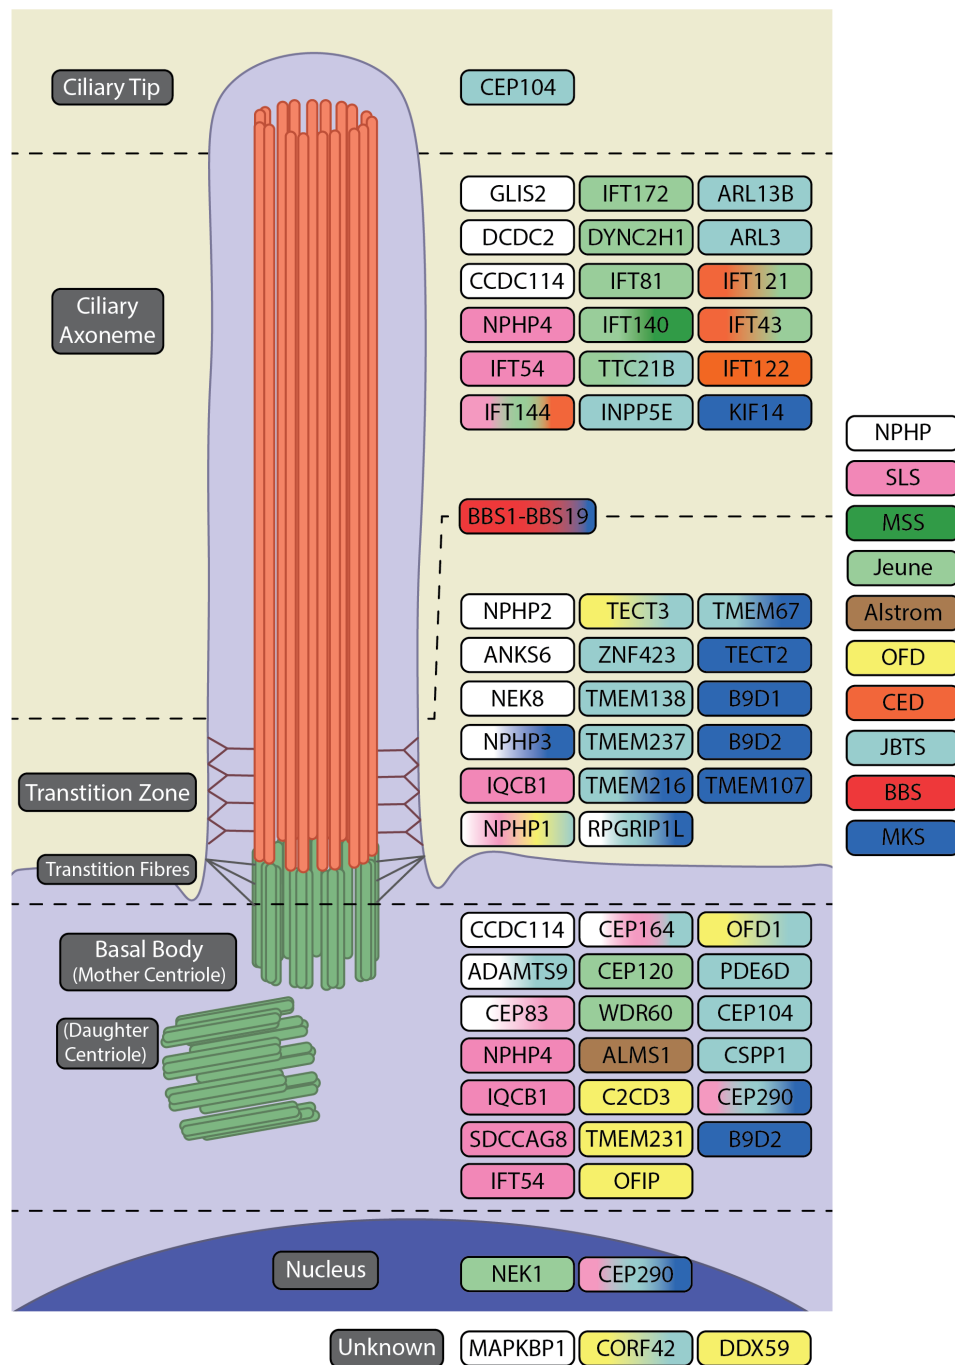

Figure 2.2 Ciliary localisation and syndromic associations of gene products associated with NPHP-RC. Genes associated with NPHP-RC are grouped according to their proposed ciliary localisation and shaded according to their syndromic associations. The intention of this figure is to highlight the vast phenotypic variability within NPHP and the emerging redundancy of eponymous syndromes. There are some interesting observations, however, such as the absence of a Jeune Syndrome phenotype and the dominance of Meckel Gruber Syndrome within the genes localised to the Transition Zone. Only those NPHP-RC genes inclusive of a kidney phenotype are listed. NPHP – isolated nephronophthisis; SLS – Senior Løken Syndrome; MSS – Mainzer Saldino Syndrome; OFD – Oral-Facial-Digital Syndrome; CED – Cranio-Ecto-Dermal Syndrome; JBTS – Joubert Syndrome; BBS – Bardet Biedl Syndrome; MKS – Meckel Gruber Syndrome. (Compiled from (Braun and Hildebrandt, 2016, Devlin and Sayer, 2019, Wolf, 2015))

the course of disease and there exists hypothesis that tubulointerstitial fibrosis is the primary, and potentially more important, disease process.(Slaats et al., 2016)

The natural history of NPHP is progression to ESRD requiring dialysis or transplantation. NPHP represents the most common genetic cause of ESRD in children and young adults under 30 years of age.(Braun and Hildebrandt, 2016, Hildebrandt, 1999, Hildebrandt et al., 2011) If diagnosed early, treatment of the secondary physiological effects of CKD (eg. hypertension, proteinuria, acidosis, bone disease) can theoretically slow the rate of progression. As the number of genes associated with NPHP-RC increases, it is becoming evident that there is a spectrum of molecular mechanisms underlying disease for which a universal treatment is unlikely to be applicable.(Srivastava et al., 2017a) As mentioned above, there also remains debate as to whether the most appropriate target of therapy should be epithelial dysfunction or the interstitial fibrosis.(Slaats et al., 2016) For these reasons there is not currently a clinically available treatment targeting the progression of the primary disease process.

2.3.1 *The Primary Cilium*

There are currently over 70 genes reported in the literature which have been associated with NPHP-RC(Braun and Hildebrandt, 2016, Devlin and Sayer, 2019).(Table 2.2,Figure 2.2) The common link between all NPHP-RC genes is their co-localisation with the primary cilium (illustrated in Figure 2.2) and centrosome.

Cilia are hair-like projections of the cell cytoplasm that extend into the surrounding extracellular space. They are highly conserved cellular organelles across evolution, between species and organs.(Nigg and Raff, 2009) Cilia are categorised into three types: motile, non-motile (also known as '*primary*' cilia) and nodal. All cilia possess an *axoneme*, a cytoskeletal backbone of nine microtubule pairs arranged in a cylinder.(Figure 2.2 and 2.3) Motile cilia are structurally distinguished by the presence of an additional pair of central microtubules connected to the outer microtubules by radial spokes, and inner and outer dynein arms which connect outer microtubules and enable the synchronised beating of sheets of motile cilia across the apical surface of a cell and tissue.(Lindemann and Lesich, 2010)(Figure 2.3) Motile cilia are present on the epithelium of airways, cerebrospinal fluid spaces, fallopian tubes and spermatozoa.

Motile cilia enable mucociliary clearance of airway secretions, movement of ova along the fallopian tube, propagation of spermatozoa and flow of CSF through the brain. During development, nodal cilia on the surface of the embryonic node beat with a unique twirling motion, generating a morphogen gradient that determines left-right axis patterning of the embryo.(Okada et al., 1999, Nonaka et al., 2002) Structurally, nodal cilia resemble primary cilia but with inner and outer dynein arms.(Horani and Ferkol, 2018)(Figure 2.3)

The first human disease linked to the human cilium was Kartagener's syndrome (OMIM #244400), discovered in 1976 upon the recognition of the absence of the linking dynein arms in the tails of immotile sperm from infertile men.(Afzelius, 1976) Kartagener's syndrome is also called primary ciliary dyskinesia (PCD), a somewhat confusing nomenclature where the adjective *primary* is used to describe the genetic (rather than acquired or 'secondary') nature of the condition and bears no reference to the primary (non-motile) cilium. PCD is an autosomal recessive condition presenting with infertility, chronic suppurative lung disease (due to impaired mucociliary clearance) and dextrocardia due to the impaired establishment of the morphogen gradient at the embryonic node during development.(Dasgupta and Amack, 2016, Nonaka et al., 2002) A large number of genetic variants have been associated with primary ciliary dyskinesia, and none of the existing reports describe a renal phenotype.(Horani and Ferkol, 2018)

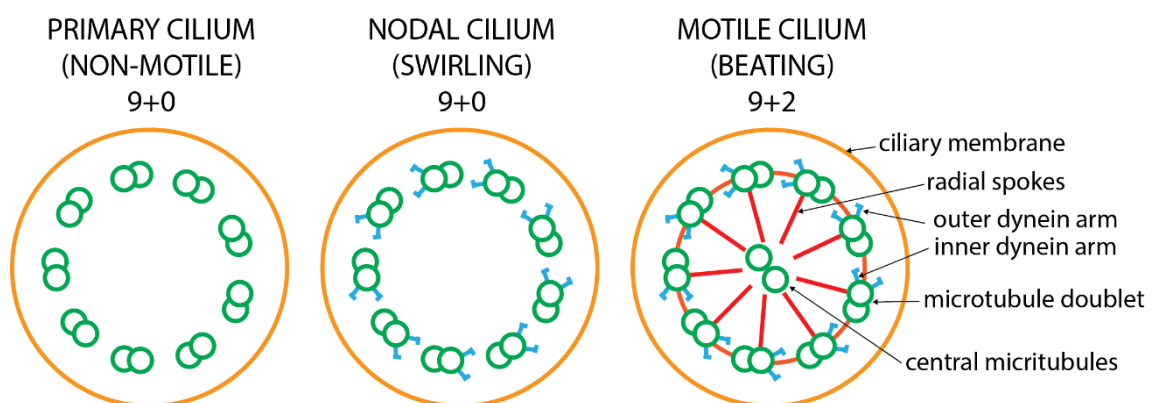

Figure 2.3 Structural differences between ciliary subtypes
 Schema of the cross sectional axonemal structure of the three different types of cilium.

Rather than performing the dynamic functions of cell propagation or movement of extracellular material along an epithelium, the *primary cilium* is involved in sampling the extracellular environment and communicating with the main body of the cell to regulate

proliferation, cell relationships and polarity.(Spasic and Jacobs, 2017, Brown and Witman, 2014, Basten and Giles, 2013) The primary cilium is also implicated in cell division as it is deconstructed prior to mitosis and reconstructed by both daughter cells following cytokinesis.(Basten and Giles, 2013, Pan et al., 2013) The observation of multisystem developmental anomalies in human patients and animal models with poorly functioning cilia strongly advocate the role of the cilium in development.

The *basal body* is the anchor of the cilium within the cell and describes the mother centriole once it has attached to the cell membrane following mitosis. This attachment is mediated by nine *transition fibres* which extend from the distal (C-terminal) end of each microtubule triplet of the basal body to the base of the ciliary membrane, marking the proximal border of the *transition zone*. The proteome of the primary cilium is unique to any other part of the cell.(Ishikawa et al., 2012)

2.3.2 The Molecular Basis of Nephronophthisis is Incompletely Understood

With the arguable exception of Bardet Biedl Syndrome, there is significant heterogeneity in the phenotypic expression and established molecular function between the genotypes identified in affected families.(Braun and Hildebrandt, 2016, Hildebrandt, 2016, Hurd and Hildebrandt, 2011) Whilst a convergent or unifying pathway responsible for the similar histological and renal phenotypes is not characterised, some of the more established genotype-specific pathways implicated are discussed below.

Maintenance of Cell-Cell and Cell-Matrix Adhesions

NPHP1 (OMIM #607100; Chromosome 2q13) was the first described gene variant in NPHP by positional cloning and is implicated in 20-25% of all NPHP disease. (Hildebrandt, 2016) Recessive *NPHP1* variants most often produce a juvenile phenotype and roughly 85% of *NPHP1* patients carrying deletions with missense variants accounting for the rest.(Otto et al., 2000, Saunier et al., 2000, Hildebrandt and Otto, 2005)

In an attempt to unify one or more common pathways within this expanding list of gene products, Sang et al. (2011) used a localisation and affinity purification (LAP) tag attached to 9 known NPHP proteins in a variety of immortalised cell cultures and determined interacting proteins by mass spectrometry. They mapped a network of

protein-protein interactions and characterised three core '*NPHPomes*'.(Sang et al., 2011) A complex of NPHP1, NPHP4 and RPGRIP1L localised to basolateral cell-cell junctions and the basal body, interacting with a separate complex including NPHP2 and NPHP3.(Sang et al., 2011) This recent, agnostic approach supports work published prior to the discovery of nephronophthisis as a ciliopathy. Before it was localised to the transition zone of the primary cilium (Fliegauf et al., 2006), NPHP1 co-immunoprecipitated with cell-cell and cell-matrix adhesions proteins in polarised IMCD3 and MDCK renal epithelial cell lines.(Benzing et al., 2001, Donaldson et al., 2000, Donaldson et al., 2002) An interaction with cell-cell junction protein and p130Cas substrate Ack1 has been characterised further emphasising a role of NPHP1 in maintaining cell-cell junctions.(Eley et al., 2008) This study also found immunofluorescent expression of NPHP1 was limited to the collecting duct in mouse kidney tissue and correlated this with the impaired concentrating ability often seen clinically.(Eley et al., 2008) Beyond this, the precise function of NPHP1 remains unknown. Interactions between NPHP1 and NPHP2,(Otto et al., 2003) NPHP3(Olbrich et al., 2003) and NPHP4(Mollet et al., 2002) have been characterised via co-immunoprecipitation and immunofluorescence.

Canonical Wnt signalling pathways and non-canonical Wnt-mediated Planar Cell Polarity (PCP).

NPHP2 (OMIM #602088) and *NPHP3* (OMIM #608002) are two NPHP genes with evidence to suggest abnormalities in canonical Wingless-related integration site (Wnt) signalling. *NPHP2* was the first gene characterised for the infantile phenotype of NPHP.(Haider et al., 1998, Otto et al., 2003) Pathogenic variants in *NPHP3* have since been identified in a cohort of patients with infantile histology in China and Europe.(Sun et al., 2016, Tory et al., 2009) Infantile NPHP is phenotypically distinguished by the atypical features of enlarged kidneys, cortical cystic changes and preservation of tubulointerstitial membrane morphology.(Tory et al., 2009) *Situs inversus* is also a feature of infantile NPHP phenotypes suggesting a role for nephrocystins in the nodal cilia during determination of left-right axis patterning, earning the name inversin for the gene product of *NPHP2*.(Simons et al., 2005) However, there exists further phenotypic variability as both *NPHP2* and *NPHP3* variants have been described in patients with juvenile and adolescent onset NPHP respectively.(Olbrich et al., 2003, Omran et al., 2000a) This

phenotypic variability has been hypothesised to be due to allelic severity with truncating variants more likely to give rise to infantile disease and non-truncating variants adolescent disease. Another hypothesis is the oligogenic, disease modifying contribution of heterozygous variants in other NPHP genes to a heterozygous or homozygous *NPHP3* gene status.(Tory et al., 2009, Hoefele et al., 2007, Devlin and Sayer, 2019)

Wnt signalling pathways are highly conserved developmental pathways across species and have also been implicated in the development of cystic kidney diseases other than NPHP.(Lancaster and Gleeson, 2010, Kim et al., 1999, MacDonald et al., 2009, Fischer et al., 2006, Schnell and Carroll, 2014) Canonical Wnt signalling begins with the binding of a Wnt ligand to a Frizzled receptor, recruiting LRP5/6 to activate Dishevelled (Dvl) which goes on to inhibit the β -catenin destruction complex. This complex of proteins includes glycogen synthase kinase 3 β (GSK3 β), axin, adenomatous polyposis coli, protein phosphatase 2A and casein kinase 1-alpha which together ubiquitinate β -catenin targeting it for proteasomic degradation.(MacDonald et al., 2009) When the β -catenin destruction complex is inhibited, an accumulation of cytosolic β -catenin enters the nucleus where it activates TCF transcription factors and subsequently genes involved in developmental signalling and proliferation.(Lancaster and Gleeson, 2010) There are numerous non-canonical pathways downstream of Wnt ligand-receptor binding but the planar cell polarity (PCP) pathway is most implicated in cystic kidney disease.(Fischer et al., 2006, Schnell and Carroll, 2014) Much less is characterised regarding non-canonical Wnt signalling which deviates from the canonical pathway at the level of Dvl and therefore operates independently of β -catenin. Membrane bound Dvl interacts with Wnt-ligand-bound Frizzled and then activates Ras homolog gene family member A (RhoA) and/or Ras-related C3 botulinum toxin 1 (Rac1). These compounds then activate Rho kinase and c-Jun N-terminal kinase which leads to transcription of genes involved in planar cell polarity and cytoskeletal rearrangement.(Lancaster and Gleeson, 2010) The primary cilium has been implicated in directing the response from the ligand-bound Frizzled receptor towards either pathway but the precise mechanism for this remains incompletely understood.

Due to the observation of cystic renal phenotypes in both Wnt gain-of-function and Wnt loss-of-function mouse models, it is likely that Wnt-signalling in the kidney requires a

precise balance for normal development and homeostasis.(Saadi-Kheddouci et al., 2001, Marose et al., 2008, Lancaster and Gleeson, 2010) This has been demonstrated in *PKDI* mediated ADPKD. The C-terminus of polycystin 1 (the *PKDI* gene product) has been demonstrated in separate studies to play a role in both inhibition and activation of canonical Wnt signalling (Kim et al., 1999) and animal models with gain or loss of polycystin 1 both develop cystic renal disease.(Lantinga-van Leeuwen et al., 2004, Thivierge et al., 2006)

NPHP2/Inversin has been demonstrated to inhibit canonical Wnt signalling by forming a complex with Dvl targeting it for degradation and thereby releasing the beta-catenin destruction complex from Dvl inhibition.(Simons et al., 2005) In HEK293T cells transfected to overexpress either or both of *NPHP2* and *NPHP3* demonstrated either protein could independently inhibit canonical Wnt signalling quantified by *TCF/LEF-1* dependant luciferase reporter activity.(Bergmann et al., 2008) Decreased canonical Wnt signalling has also been reported in an *Ahi1* knockout mouse, an animal model for classical Joubert Syndrome including a classical NPHP renal phenotype.(Lancaster et al., 2009) Furthermore co-immunoprecipitation and yeast two-hybrid cDNA library screening identified and characterised an interaction between *Glis2* and β -catenin and also demonstrated that *Glis2* acts as a repressor of TCF mediated transcriptional activation, as well as that of its own target gene *CCND1*.(Kim et al., 2007)

Unlike cytosolic Dvl, membrane bound Dvl (implicated in non-canonical Wnt signalling) appears immune to inversin mediated degradation and thus, inversin performs the role of a 'switch' between the two Wnt pathways.(Simons et al., 2005) A similar mechanism has been established for *NPHP3*.(Bergmann et al., 2008) Other ciliopathy genes have been associated with the non-canonical pathway including BBS proteins, HNF1 β , and OFD1, supporting a role for Wnt signalling in ciliopathy pathogenesis.(Lancaster and Gleeson, 2010)

Exactly how the balance between canonical and non-canonical Wnt signalling might lead to cystic kidney disease is not known. Defective orientation of tubular cell mitosis has been postulated to play a role with the observation of disturbed mitotic angles observed in *HNF1 β* mutant mice and *Pck* rats (*Pkhd1* mutant orthologue).(Fischer et al., 2006) As

described in subsequent sections on mammalian kidney development, multiple Wnt ligands play an important role in kidney development.(see Section 2.5.2) Over the course of nephron development, a shift from canonical to non-canonical dominant signalling is essential and disruption in this balance may give rise to developmental renal anomalies such as NPHP.(Park et al., 2007) Indeed, this may explain why *NPHP2/Inversin* and *NPHP3* variants (with their links to early Wnt-signal regulation) give rise to much earlier disease than other genotypes.

The primary cilium is involved in hedgehog signalling, which is dysfunctional in NPHP

Another of the Sang et al NPHPomes was a complex of co-purifying proteins including MKS1, MKS6 and TCTN2, found to localise to the base of the cilium and also interact with AHI1/Joubertin.(Sang et al., 2011) MKS1 has been hypothesised to affect abnormal hedgehog signalling in the developmental patterning of the limb and brain in the *krc* mouse.(Weatherbee et al., 2009) *Tctn2*^{-/-} mice demonstrated severely abnormal phenotype consistent with abnormal hedgehog signalling (fully penetrant neural tube defects, exencephaly, polydactyly, microphthalmia and cleft palate), reduced transcription of hedgehog target genes *Ptc1* and *Gli1* and also increased amounts of unprocessed Gli3 protein, all consistent with reduced hedgehog responsiveness. It is possible that the MKS1 NPHPome is an important contributor to hedgehog pathway signalling. (Sang et al., 2011) In separate work *GLIS2* is established as an NPHP genotype and recapitulates a classical NPHP histology in 4 week old mutant mouse model.(Attanasio et al., 2007) Upregulated gene pathways in *Glis2* mutant mice include epithelial to mesenchymal transition, apoptosis, fibrosis, cell cycle inhibition as well as a role for Glis2 to act in a feed forward loop on Gli1 transcription targets (eg. *Bmp4*, *Pax2*, *Sall1*, *Ccnd1* and *N-myc*).(Attanasio et al., 2007)

The evidence for dysfunctional hedgehog signalling in Joubert Syndrome is conflicting, with animals demonstrating abnormal hedgehog signalling phenotype on a molecular level (Hynes et al., 2014, Damerla et al., 2015) but often incomplete JBTS phenotypes including normal dorsoventral patterning of the neural tube, a developmental process believed to rely heavily on intact hedgehog signalling.(Damerla et al., 2015, Abdelhamed et al., 2013, Hynes et al., 2014) It is possible that this variability in molecular and developmental hedgehog signalling phenotype between reports is due to variability in the

severity of disruption to the signalling pathway, tissue specific effects of different genes or technical difficulties in measuring hedgehog signalling activity in research models.

Another reason for this variability could be interspecies differences in hedgehog signal transduction. Mouse studies suggest that Gli2 is the principle transcription activator whilst Gli3 the principle transcription repressor whilst both proteins are capable of both functions.(Matisse et al., 1998, Litingtung and Chiang, 2000) Whilst Gli1 is essential for normal Hh signalling in zebrafish(Karlstrom et al., 2003), it has no repressor function in mammals and contributes only modestly to Gli2 mediated transcriptional activation.(Park et al., 2000) In amphioxus, alternatively spliced isoforms of the one *Ci* (*Gli* ortholog) gene act as repressors or activators.(Shimeld et al., 2007) Finally in mammals, post-translational proteolysis of multiple *Gli* genes is controlled by phosphorylation of the C-terminal to determine repressor or activator function.(Briscoe and Therond, 2013) Whilst existing animal ciliopathy models strongly suggest disturbances in hedgehog signalling play a role in disease, high interspecies variation in hedgehog signalling transduction would suggest ongoing research is best performed in a human cellular functional genomic model.

DNA Damage Response Pathways and Cell Cycle Arrest

The third complex identified in the Sang et al (2011) report illustrated that CEP290 is required to recruit NPHP5 to the centrosome prior to cell division. The cilium is deconstructed prior to mitosis, at which point the basal body of the cilium becomes the mother centrosome.(Basten and Giles, 2013, Pan et al., 2013) It is therefore highly likely that mutant basal body proteins could disrupt the mitotic process. In one report, *Cep290* mutant mice demonstrated supra-numerary centrioles, increased DNA replication stress and DNA damage, a phenotype that was rescued by CDK inhibitors.(Slaats et al., 2015) Other human NPHP genotypes implicated in increasing DNA damage response include *CEP164*(Sivasubramanian et al., 2008), *ZNF423*(Chaki et al., 2012), *OFD1*, *SDCCAG8*(Otto et al., 2010) and *NEK8*(Choi et al., 2013a). CDK5 inhibitors have also been demonstrated to successfully retard histological disease progression in a *NEK8* mutant mouse model.(Husson et al., 2016) and represent a promising targeted therapy not only in the NPHP literature but also in ADPKD.(Bukanov et al., 2012, Bukanov et al., 2006, Moreno et al., 2008, Booiij et al., 2017)

2.3.3 *Intraflagellar Transport*

There is no mechanism for protein synthesis within the cilium so all proteins must be manufactured in the cell cytoplasm and transported into the cilium. The transition zone represents the most proximal zone of the cilium. It is distinguished by bifid proteins (called Y-links) which extend from the midpoint of the axonemal microtubular doublets to the ciliary membrane.(Figure 2.3) Here they attach to beads giving the appearance of multiple studded necklaces around the base of the cilium (the *ciliary necklace*). (Fisch and Dupuis-Williams, 2011) The term '*ciliary gate*' refers to the transition fibres and transition zone. This label refers to the function of the ciliary gate as a regulator of protein entry to (and exit from) the ciliary cytoplasm. The transition fibres are also important in the recruitment of the necessary proteins to the distal centriole to initiate and promote ciliogenesis.(Garcia-Gonzalo and Reiter, 2016) The protein subunits from which the transition fibres and Y-links of the ciliary gate are composed are well represented in lists of gene products associated with ciliopathy syndromes.(Garcia-Gonzalo and Reiter, 2016, Hildebrandt, 2016)(Figure 2.2)

There are multiple mechanisms for the entry of cilia-targeted proteins to the ciliary space. Membrane bound or transmembrane proteins are targeted to the cilium via transport of vesicles direct from the Golgi apparatus.(Nachury et al., 2010) It is also likely that specific amino acid motifs (called ciliary localisation sequences – CLS) identify proteins for ciliary localisation.(Bloodgood, 2000, Garcia-Gonzalo and Reiter, 2012) These CLS interact with intraflagellar transport (IFT) and Bardet Biedl Syndrome (BBS) proteins at the junction of the transition fibres and ciliary membrane and facilitate transition of these proteins across the ciliary gate by mechanisms that are not clearly characterised.(Vieira et al., 2006, Hou et al., 2007, Qin et al., 2011)

Because the basal body lumen is obstructed with electron dense, centrin-2 containing structures, the only path for soluble proteins into the cilium is across the transition fibres.(Fisch and Dupuis-Williams, 2011) There are multiple described mechanisms by which proteins can make this transition. IFT protein levels have been observed to swell beneath the *Chlamydomonas* flagellum at the transition fibres before a controlled release or 'avalanching' into the ciliary space.(Ludington et al., 2013) This may be mediated by a phosphorylation dependent, Ras-related nuclear (Ran-GTP) protein gradient capable of

sensing flagellar length and therefore self-regulating the availability of construction machinery.(Ludington et al., 2013, Dishinger et al., 2010) Perhaps the most important mechanism of soluble protein transfer into the ciliary cytoplasm is, as for membrane bound proteins, the ability to interact with IFT proteins, IFT motors, BBSome proteins and other proteins such as importin-2.(Garcia-Gonzalo and Reiter, 2012, Dishinger et al., 2010, Hou et al., 2007) Many of the above-described mechanisms illustrate similarities between ciliary and nuclear protein targeting.(Verhey et al., 2011) Indeed, nucleoporins have been found to localise at the ciliary base (Kee et al., 2012) and kinesin motors have been observed shuttling transcription factors between ciliary and nuclear compartments.(Chennathukuzhi et al., 2003, Morris et al., 2004, Dishinger et al., 2010) Exactly how this translates to disease mechanism is yet to be elucidated but it is clear that ciliary protein importation is a complex and highly regulated process which is partly dependent on IFT proteins.

Kinesin protein multimers ascend the ciliary axoneme driving anterograde IFT whilst dynein protein complexes descend the cilium driving retrograde IFT.

Once across the transition fibres a system of IFT moves proteins up and down the cilium along the axoneme. Transport of proteins from the base to the tip is called anterograde IFT and the transport of proteins in the reverse direction is called retrograde IFT.(Kozminski et al., 1993, Rosenbaum and Witman, 2002) Anterograde IFT is performed by a kinesin-II motor made of three protein subunits (KIF3A, KIF3B and KAP) whilst retrograde IFT is performed by a more complex dynein motor composed of eight protein subunits.(Kozminski et al., 1995, Pazour et al., 1999) These motors interact with the ciliary axoneme and with IFT protein complexes (which in turn interact with IFT cargo proteins and the BBSome) to form IFT trains.(Rosenbaum and Witman, 2002) Anterograde and retrograde motors have been demonstrated to associate with the B- and A- tubules of the microtubule doublets respectively which prevents collision of motors moving in different directions.(Stepanek and Pigino, 2016)

The function and dysfunction of the heterotrimeric kinesin-II was first demonstrated using a temperature controlled *fla-10* mutant (orthologue to human *KIF3A*) *Chlamydomonas* model.(Kozminski et al., 1995) When the temperature was raised to restrict *fla-10* expression, cessation of IFT was observed and the flagellum started to

shorten.(Kozminski et al., 1995) This indicates that not only is anterograde IFT required for ciliary construction, but also for maintenance of the mature cilium. *Kif3a* knockout mouse models have since demonstrated absence or severe shorting of poorly motile cilia at the embryonic node. (Marszalek et al., 1999, Takeda et al., 1999) The phenotype of these mice included *situs inversus*, abnormal mesodermal patterning and embryonic lethality.(Marszalek et al., 1999, Takeda et al., 1999)

Retrograde IFT is driven by a cytoplasmic dynein 2 multimer motor and mutations in subunits of this motor give rise to a classical ciliary morphology of shortened cilia with bulbous tips.(Pazour et al., 1999, Collet et al., 1998, Signor et al., 1999, Wicks et al., 2000, May et al., 2005) The expanded ciliary tip represents the accumulation of retrograde IFT cargo unable to descend the cilium. The shortened cilium is thought to arise from the unavailability of anterograde IFT machinery held up in the ciliary tip, which would otherwise be recycled for ciliary maintenance.(Pazour et al., 1999) The recycling of IFT components is evidenced by the observation of ongoing IFT despite the arrest of cellular protein synthesis by aminoglycoside toxicity.(Iomini et al., 2001)

IFT proteins are separated into IFT-A and IFT-B groups.

Both anterograde and retrograde motors interact with ciliary proteins via bridging IFT proteins.(Rosenbaum and Witman, 2002, Lechtreck, 2015, Taschner and Lorentzen, 2016)(Table 2.3) IFT proteins are rich in tetratricopeptide repeats, WD40 domains, and coiled-coil domains which are all well characterised protein-protein interaction domains.(Taschner et al., 2012) Whilst many of the protein-protein interactions have been identified in yeast two hybrid analyses and similar protein-protein association experiments, many of the interactions between IFT proteins have since been demonstrated to require the interaction of cargo with the assembled IFT complex.(Taschner et al., 2016)

IFT proteins rely on protein components of the transition fibres for appropriate localisation in the cilium both during ciliogenesis and in the ciliary maintenance state. For example, in RPE cell monolayers, *Cep164* siRNA treatment was associated with reduced localisation of IFT88 at the transition zone of the cilium without a reduction in the amount of *IFT88* expression.(Schmidt et al., 2012) In a separate report, *CCDC41* knockdown reduced IFT20 localisation to the basal body and reduced docking of ciliary

Figure 2.4 The role of IFT140 in the primary cilium

The primary cilium is a hair-like projection from the apical surface of the renal epithelial cell. With no internal protein manufacturing equipment, the cilium imports proteins from the main body of the cell and transports them up and down the cilium using intraflagellar transport (IFT). IFT140 Forms a core component of the IFT-A complex which binds IFT cargo to the dynein motor which descends the ciliary axoneme, returning its cargo the base of the cilium for export into the main cell cytoplasm.

vesicles.(Joo et al., 2013) In mouse embryonic fibroblasts treated with *C2cd3* siRNA recruitment of IFT88 and IFT52 to the basal body was reduced.(Ye et al., 2014) Finally, extrapolating from a *C. elegans* model, transition protein FBF1 is believed to interact with the IFT-B complex of assembled IFT proteins to mediate ciliary import.(Wei et al., 2013)

IFT-B proteins link IFT cargo to kinesin motors in anterograde IFT.

There are 16 proteins within the IFT-B complex which are further grouped into a *core* subunit (IFT-B1: IFT88,81,74,70,56,52,46,27,25 and 22) and a *peripheral* subunit (IFT-B2: IFT172,80,57,54,38 and 20). (Table 2.3) Members of the IFT-B1 complex are defined by strong hydrophobic bonds that resist dissociation at saline concentrations greater than 2 molar.(Taschner et al., 2014) Whilst peripheral IFT-B2 proteins dissociate from the IFT-B complex at a lower salinity (reflecting weaker associations), they are capable of independently forming their own complex in the absence of IFT-B1 proteins.(Taschner et al., 2016) The two subcomplexes interact at IFT88/52 and IFT38/57.(Taschner et al., 2016)

Mutations in IFT-B proteins demonstrate absent or very short cilia, similar to the severe ciliogenesis defects seen in kinesin-II mutants. An *IFT88* mutant *C. reinhardtii* model demonstrated absent flagella and the mouse and human homologue gene was identified to be *Tg737*, for which a mouse model demonstrates early onset polycystic kidney disease (Pazour et al., 2000) potentially implicating IFT dysfunction as a cause of PKD. An *IFT172* knockout *Tetrahymena* demonstrated a similar ciliary morphology however the introduction of a partially truncated rescue construct developed short cilia with accumulation of IFT88 at the ciliary tip, implicating IFT172 in the rearrangement of retrograde IFT particles in the transition between anterograde and retrograde IFT.(Tsao and Gorovsky, 2008) All of *IFT52*(Richey and Qin, 2012), *IFT46*(Hou et al., 2007) and *IFT74*(Brown et al., 2015) null mutants also demonstrate severely impaired ciliogenesis in *C. reinhardtii* models.

Other specific functions of IFT-B proteins include the following.[Reviewed in(Taschner and Lorentzen, 2016)]

- IFT25 and IFT27 are essential in the export of Sonic hedgehog (Shh) signalling mediators from the cilium and produce defects in signalling in mouse models. These proteins may also assist in the export of BBSome proteins which accumulate in the ciliary space in knockout mutants. Variants in *IFT27* have been identified in patients with BBS.
- IFT20 localises to the Golgi apparatus and is thought to associate with ciliary membrane bound proteins, targeting them for ciliary localisation. The precise mechanism for this is not identified.
- Transport of tubulin heterodimers for ciliogenesis and maintenance via an IFT81/74 binding site and an IFT54 binding site.

IFT-A proteins participate in retrograde IFT.

The IFT-A proteins are smaller in number with three proteins forming a *core* subcomplex (IFT140, IFT144 and IFT122, Table 3).(Mukhopadhyay et al., 2010, Behal et al., 2012) The core proteins maintain their association in the presence of a mutant *non-core* protein (IFT139, IFT121 and IFT43, Table 3).(Mukhopadhyay et al., 2010, Behal et al., 2012) Mutations in core IFT-A proteins don't disrupt the other core proteins, however, they can destabilise and deplete the non-core proteins from the IFT-A complex.(Behal et al., 2012)

In mouse germline knockout models of IFT-A genes *IFT44*, *IFT140*, *IFT139*, *IFT122* and *IFT121* result in embryonic lethality or neonatal death with profound defects in skeletal, ophthalmic, craniofacial and neurological development.(Tran et al., 2008, Cortellino et al., 2009, Liem et al., 2012, Mill et al., 2011, Miller et al., 2013, Yuan and Yang, 2015) No mouse model of *IFT43* has been published but variants in all IFT-A genes (including *IFT43*) have been described in patients with skeletal ciliopathies.(Perrault et al., 2012, Schmidts et al., 2013, Bredrup et al., 2011, Walczak-Sztulpa et al., 2010, Davis et al., 2011, Smith et al., 2016, Arts et al., 2011) *Chlamydomonas* temperature-sensitive *IFT144*, *IFT139* and *IFT121* mutants demonstrate shortened cilia with a bulbous tip (Iomini et al., 2001, Blacque et al., 2006, Piperno et al., 1998), similar to dynein 2 mutant models. (Pazour et al., 1999, Collet et al., 1998, Signor et al., 1999, Wicks et al., 2000, May et al., 2005) IFT-A mutant *Chlamydomonas* models also demonstrate reduced retrograde transport velocities.(Piperno et al., 1998) Collectively these observations demonstrate the indispensable nature of IFT-A proteins for retrograde IFT.

The IFT-A complex has been strongly implicated in Sonic hedgehog (Shh) signalling (Liu et al., 2005, Huangfu et al., 2003, Jonassen et al., 2012). With Shh ligand unbound, the Patched (Ptc) receptor inhibits activity of Smoothed (Smo) G-protein coupled receptors in and around the ciliary membrane.(Stone et al., 1996) Binding of the Shh ligand releases this inhibition and allows Smo to become phosphorylated and migrate into the cilium whilst Ptc and other Shh repressors leave the cilium and peri-ciliary membrane.(Briscoe and Therond, 2013) Activated Smo inhibits C-terminal phosphorylation the Gli family of zinc finger proteins (Gli1, Gli2 and Gli3) by protein kinase A, GSK3 β and casein kinase 1 within the cilium. Phosphorylation of Gli proteins results in partial proteolytic degradation and the shortened proteins are translocated to the nucleus where they act as transcriptional repressors of Shh targets.(Briscoe and Therond, 2013) Smo-related inhibition of this phosphorylation allows the transcription factors to migrate to the nucleus free from to proteolytic breakdown where they act as transcriptional activators for the same gene targets.(Briscoe and Therond, 2013) Gene targets have been identified using chromatin immunoprecipitation and include components of the Shh pathway itself (eg. *Ptc* and the *Gli* gene family) and genes involved in developmental patterning in a tissue specific manner.(Vokes et al., 2007, Vokes et al., 2008)

IFT-A Core	IFT-A Non-Core	IFT-B1 (Core)	IFT-B2 (Periph)
IFT144	IFT139	IFT88	IFT172

		IFT56	IFT38
		IFT52	IFT20
		IFT46	
		IFT27	
		IFT25	
		IFT22	

Table 2.3 Intraflagellar transport proteins classified according to subcomplex (adapted from (Taschner and Lorentzen, 2016))

Many IFT-A mutants exhibit activation of the Shh pathway in the absence of ligand binding to Ptc(Tran et al., 2008, Qin et al., 2011, Liem et al., 2012, Jonassen et al., 2012, Miller et al., 2013) but some models, along with the Dynein-2 motor mutant have documented reduced Shh signalling.(Liem et al., 2012, Ocbina et al., 2011, Cortellino et al., 2009) Mouse models with reduced signalling are observed to have more severe

problems with ciliogenesis and this is postulated as the reason for reduced Shh signalling. However, at least one dynein-2 (DYNC2H1) mutant mouse model manifests the same ciliary morphology as IFT-A mutants but with *reduced* Shh signalling suggesting that defective retrograde IFT is probably not the only mechanism moderating Shh pathways within cilia.(Ocbina et al., 2011) A role has been established for IFT144 proteins in the ciliary import of Smo, Arl13b and adenylyl cyclase III which is required for the phosphorylation of Gli gene products to target them for proteolytic degradation to repressor isoforms.(Liem et al., 2012)

Another potential mechanism of Shh dysfunction was discovered by tandem affinity purification and immunofluorescence suggesting the core IFT-A complex (potentially IFT122) is responsible for the ciliary import of Tubby like protein 3 (TULP3)(Mukhopadhyay et al., 2010, Qin et al., 2011) The same group demonstrated TULP3 is responsible for ciliary import of G protein coupled receptors, including Gpr161 but *not* including Smo. Gpr161 was then shown to be a negative regulator of Shh signalling by findings of increased expression of Shh transcriptional targets *Ptc* and *Gli1* as well as a ventralised neural tube in a *Gpr161* mutant.(Mukhopadhyay et al., 2010, Mukhopadhyay et al., 2013) Further study of the this model identified (i) that Shh over-activation was Smo independent, (ii) that treatment with Shh ligands lead to ciliary exportation of Gpr161 and most importantly (iii) that basal activity of Gpr161 leads to increased cyclic AMP levels (Mukhopadhyay et al., 2013) which is one of the closest molecular links between IFT-A dysfunction and polycystic kidney disease reported in the literature.(Pazour et al., 2000)

Collectively, this research suggests a role beyond retrograde IFT for IFT-A proteins, namely ciliary importation of proteins. Furthermore, a *C. elegans* model in which hypomorphic mutations in *IFT144* or *BBS1* that disrupted their interaction, led to decreased ciliary import of multiple BBSome proteins and the absence of any anterograde movement of the BBSome.(Wei et al., 2012) IFT assembly at the ciliary base was normal, however accumulation of IFT machinery at the ciliary tip was hypothesised to be due to the absence of the BBSome to moderate this transition.(Wei et al., 2012) This not only suggests that IFT proteins are assembled outside the cilia but also that defective retrograde IFT might occur indirectly due to reduced importation of accessory components to IFT,

rather than the more simplistic failure of cargo proteins to associate with the IFT-A complex.

The precise details of interactions between IFT-A proteins and the mechanisms by which mutations in these proteins might disturb Shh signalling are uncharacterised.

Pathogenic variants in IFT140 are associated with NPHP related ciliopathies.

Case reports and series of patients with variants in *IFT140* have established a phenotypic association with Mainzer-Saldino Syndrome (MSS), Jeune Asphyxiating Thoracic Dystrophy (JATD) and non-syndromic retinal dystrophy.(Perrault et al., 2012, Schmidts et al., 2013, Xu et al., 2015) Expanding the phenotypic spectrum further, recent case of Opitz Trigonoccephaly C Syndrome has been reported with biallelic *IFT140* variants.(Pena-Padilla et al., 2016) In patients with Jeune syndrome, biallelic *IFT140* variant genotype confers a more severe renal and retinal phenotype, and a more favourable skeletal phenotype compared to other genes.(Schmidts et al., 2013) This is consistent with the finding that IFT140 is most heavily expressed in the developing retina and kidney during murine foetal development.(Schmidts et al., 2013)

IFT140 is a 1462 amino acid protein with 31 exons. It possesses five WD40 repeat domains and nine tetratricopeptide repeats typical of IFT proteins and indicative of involvement in IFT protein multimers and extensive protein-protein interactions.(Taschner and Lorentzen, 2016) Within the IFT-A core complex, *Chlamydomonas*, yeast two-hybrid and co-expression/pulldown techniques suggest IFT140 interacts directly with IFT144 and IFT122.(Behal et al., 2012)

The spectrum of *IFT140* variants includes non-truncating missense variants, and rare truncating variants including splice site, frameshift and non-sense variants.(Schmidts et al., 2013) All reported non-consanguineous cases carry compound heterozygous variants.(Perrault et al., 2012, Schmidts et al., 2013) In the Perrault et al (2012) cohort, variants associated with MSS were located at the N-terminus of the protein, whereas variants associated with JATD were more evenly distributed throughout the whole gene. The most severe published *IFT140* phenotype describes an infant with a missense donor splice variant at exon 24 *in trans* with a 17 bp deletion in exon 1, presenting with a

combined MSS and Opitz trigonocephaly C syndrome.(Pena-Padilla et al., 2016) This infant survived 31 days. No patient has been reported with two truncating variants indicating that some protein function is required for survival of the embryo.

An *IFT140* mutant mouse model, the *Cauli* mouse, was identified by comprehensive, phenotype driven ENU mutagenesis screening and carries homozygous missense mutations in exon 19 at position 2564 (T to A) affecting a change from isoleucine to lysine at amino acid position 855.(Miller et al., 2013) Cilia morphology reflected abnormal retrograde IFT (shortened cilia with bulbous tip) without *any* ciliary IFT140 expression.(Miller et al., 2013) Numerous, profound, skeletal developmental defects dominated the phenotype accompanied by spina bifida, exencephaly, digital abnormalities, cardiac anomalies and embryonic lethality.(Miller et al., 2013) No renal phenotype was observed but may have developed if the embryos had survived longer. Why a missense mutation resulted in such a severe phenotype is not known.

To overcome the difficulty posed by early embryonic lethality in studying renal manifestations of *IFT140* mutation, a HoxB7-Cre driven selective knockout was engineered by Jonassen et al (2012), which produced a selective deletion of *IFT140* in the CD and manifest cystic changes in this segment by post-natal day 5. This model demonstrated increased mitotic index in cystic collecting ducts, no IFT140 association with the mitotic spindle during mitosis and preserved mitotic spindle orientation in the CD.(Jonassen et al., 2012)

Immunohistochemical analysis of limb buds in the *Cauli* mouse demonstrated ectopic Sonic hedgehog expression in the anterior limb bud margin.(Miller et al., 2013) The HoxB7-Cre driven null mutant model demonstrated increased expression of non-canonical Wnt and Sonic hedgehog signalling pathways as well as increased Hippo and complement activity following the onset of cystic disease, hypothesising that this pathway activity was a secondary effect attempting to constrain hyperproliferation rather than a primary consequence of ciliary dysfunction.(Jonassen et al., 2012)

In *Drosophila* flies carrying mutations in the orthologue for *IFT140* (called *rempA* or reduced mechanoreceptor A), cilia adopt a defective retrograde IFT morphology

(shortened with bulbous tip) and failure to localise TRPV4 to the cilium, whereas a dynein mutant displayed mislocalisation of TRPV4 within the cilia.(Lee et al., 2008) Once again, this advocates a role for IFT140 in importation of ciliary proteins across the ciliary gate.

Patient-derived, FLAG-tagged *IFT140* variants have also been expressed in transfected RPE cell lines and demonstrated loss of basal body localisation, however wild type IFT140 localisation in fibroblasts from two patients was consistent with control along the ciliary axoneme.(Perrault et al., 2012) Ciliary number was reduced in mutant fibroblasts and mutant cilia demonstrated accumulation of IFT-B components at the bulbous tip characteristic of defective retrograde transport.(Perrault et al., 2012)

In summary, *IFT140* variants have been associated with nephronophthisis related ciliopathies, particularly skeletal ciliopathies. The precise functional genomic characterisation of this protein is in its early stages and has relied primarily on non-human models which have suggested roles in retrograde IFT and import of specific ciliary proteins.

2.4 Steroid Resistant Nephrotic Syndrome

Nephrotic syndrome (NS) describes the clinical sequence of profound proteinuria sufficient to lead to hypoproteinaemia. This is a potentially life-threatening condition as the proteins lost in the urine support immune function and prevent spontaneous thrombosis, leaving patients vulnerable to sepsis and blood clots.(Kerlin et al., 2014, McIntyre and Craig, 1998) The loss of plasma oncotic pressure reduces interstitial fluid reabsorption in the micro-circulation leading to tissue oedema.

In children with NS over 80-90% have a systemic, circulating aetiology with no suspected intrinsic renal component.(Noone et al., 2018, Greenbaum et al., 2012, Sinha et al., 2015, Teeninga et al., 2013, Yoshikawa et al., 2015) These patients experience relapsing and remitting episodes of proteinuria with eventual, spontaneous resolution of the primary disease stimulus. Based on the frequent response to immunosuppression, it is believed that this idiopathic stimulus is produced by the immune system.(Franke et al., 2019, Greenbaum et al., 2012, Noone et al., 2018) The first line immunosuppressive therapy is corticosteroids which gives rise to the diagnostic sub-category of steroid resistant nephrotic syndrome (SRNS) for those who don't respond within 4-6 weeks.

Steroid resistant nephrotic syndrome (SRNS) is the second most common cause of progressive CKD in children (Fletcher et al., 2013, NAPRTCS, 2014) and invariably leads to the need for dialysis or kidney transplantation.(D'Agati et al., 2011) The most common histological lesion in SRNS is focal segmental glomerulosclerosis (FSGS), although patients presenting in infancy may demonstrate diffuse mesangial sclerosis or collapsing glomerulopathy.(Hildebrandt and Heeringa, 2009, Sadowski et al., 2015) At an electron microscopic level, NS is characterised by morphological effacement of interdigitating podocyte foot processes. In the healthy state, these foot processes are bridged by a network of proteins called the slit diaphragm.(Noone et al., 2018, Fissell and Miner, 2018, Arif and Nihalani, 2013) In active NS this structure is lost along with the size and charge selectivity of the glomerular filtration barrier, allowing negatively charged proteins to be filtered into the urine.

Whilst SRNS patients may still have a non-genetic, systemic circulating aetiology, up to 45% of patients under 25 years of age with SRNS carry a genetic variant associated with their disease.(Sadowski et al., 2015, Warejko et al., 2018) At present there are over 60 genes associated with SRNS in adults and children

The earlier the onset of disease, the more likely a genetic aetiology. In genetic disease, the pathogenesis is intrinsic to the podocytes with most known gene products contributing to essential developmental or homeostatic podocyte pathways.(Löwik et al., 2009, Ashraf et al., 2018, Lovric et al., 2016, Warejko et al., 2018, Machuca et al., 2009) Genetic forms of SRNS are less likely to respond to second and third line immunosuppressive treatments and therefore these patients are usually selected for genetic screening.(Giglio et al., 2015, Ruf et al., 2004, Hinkes et al., 2007) Targeted therapy exists for only a few and progression to end-stage kidney disease is inevitable. Disease recurrence is not seen following kidney transplantation.

2.4.1 Molecular Biology of SRNS

Podocytes wrap themselves around glomerular capillaries using primary and secondary foot processes to form a three-dimensional layer of interdigitating cells.(Figure 2.1) The primary processes are supported by a microtubular cytoskeleton and the secondary interdigitating foot processes are supported by an actin cytoskeleton.(Welsh and Saleem,

2011) This morphology serves to maximise the surface area for cell-cell and cell-matrix adhesion, given the podocytes must withstand the force of glomerular filtration emanating from the capillaries.(Schell and Huber, 2017, Lennon et al., 2014) Like any blood vessel, glomerular capillaries are dynamic structures which can expand and retract in response to intravascular hydrostatic forces. In order to accommodate changes in the glomerular capillary surface area, podocytes must be able to readily remodel their cytoskeleton and adhesion. This is especially prudent in the setting of recovery from glomerular injury where *in vivo* live imaging has demonstrated podocytes increase their motility.(Hackl et al., 2013) The effacement of foot processes seen in NS represents a loss of cytoskeletal organisation. As more and more SRNS associated genes are discovered, a more granular understanding of the heterogeneous molecular basis underlying SRNS is evolving and centring around regulation of the actin cytoskeleton. A list of genes associated with SRNS is provided in Table 2.4.

The slit diaphragm is anchored to and regulates the actin cytoskeleton

Slit diaphragm proteins nephrin and podocin were the first discovered mutated gene products giving rise to SRNS.(Kestila et al., 1998, Boute et al., 2000) Nephrin (encoded by *NPHS1*), is a transmembrane protein with a large extracellular region containing eight IgG-like domains. Nephrin is the backbone of the slit diaphragm, coordinating recruitment of other slit diaphragm associated proteins both extra- and intracellularly.(Saleem et al., 2002, Schwarz et al., 2001, Sellin et al., 2003) Podocin (encoded by *NPHS2*) extends from sturdy lipid rafts in the podocyte membrane to bind and stabilise the slit diaphragm via nephrin.(Huber et al., 2003b) Initially slit diaphragm protein complexes were believed to perform a purely structural role as a filtration barrier, however, they have subsequently been characterised as a specialised cell-cell junction which communicates with polarity complexes (Hartleben et al., 2008, Scott et al., 2012, Ebarasi et al., 2015) and regulates the actin cytoskeleton.

A series of proteins that assemble intracellularly around the nephrin-podocin complex are encoded by SRNS-associated genes including *CD2AP*, *TRPC6*, *PLCE1*, *MAGI2* and *PODXL*.(Huber et al., 2003a, Winn et al., 2005, Hinkes et al., 2006, Barua et al., 2014a, Reiser et al., 2005, Lehtonen et al., 2005) *CD2AP* binds the nephrin-

Table 2.4 Genotypes associated with SRNS

Adapted from (Preston et al., 2019) and (Lovric et al., 2016). AD: autosomal dominant, AR: autosomal recessive, XLR: X-linked recessive, XL*: X linked with affected carriers observed, Mit: mitochondrial inheritance, FSGS: focal segmental glomerulosclerosis, CG: collapsing glomerulopathy, DMS: diffuse mesangial sclerosis, ER: endoplasmic reticulum, IFTA: interstitial fibrosis and tubular atrophy, MCD: minimal change disease, SSNS: steroid sensitive nephrotic syndrome, SDNS: steroid dependent nephrotic syndrome, SRNS: steroid resistant nephrotic syndrome, CNS: congenital nephrotic syndrome, SNHL: sensorineural hearing loss, PI3K: phosphoinositol 3 kinase, DAG: diacylglycerol, GH: growth hormone, MELAS: mitochondrial encephalopathy, lactic acidosis, stroke-like episodes, ID: intellectual disability, , DSD: disorder of sexual development, MPGN: membranoproliferative glomerulonephritis, EB: epidermolysis bullosa, IS: immunosuppression. (3 of 3)

podocin complex to the actin cytoskeleton via ANLN. (Schwarz et al., 2001, Gbadegesin et al., 2014) CD2AP recruits actin capping protein and cortactin which are involved in the formation of new actin structures at the cell periphery, enabling cell migration. (Zhao et al., 2013) Phosphorylated tyrosine residues in the cytoplasmic tail of nephrin recruit NCK1/2 proteins (Verma et al., 2006) and in combination CD2AP, activate the PI3K/AKT pathway. In addition to promotion of cell survival, the PI3K/AKT pathway activates CFL1, which also plays a role in actin remodelling during podocyte recovery from injury. (Garg et al., 2010, Huber et al., 2003a, Cooper et al., 2018) The FYN kinase responsible for phosphorylating cytoplasmic nephrin also phosphorylates tyrosine residues on TRPC6, opening the ion channel to calcium influx. (Hisatsune et al., 2004, Reiser et al., 2005) Furthermore, wild type podocin can attenuate TRPC6 calcium influx in the setting of membrane stretch (Anderson et al., 2013), suggesting the ability of the slit diaphragm to respond to the mechanosensory cues in the intercellular junction and respond with calcium influx and actin remodelling. (Greka and Mundel, 2012, Jiang et al., 2011) PLCE1 is also a slit diaphragm associated protein with a demonstrable role in podocyte calcium balance. PLCE1 binds to the nephron-podocin intracellular complex indirectly via IQGAP1. PLCE1 hydrolyses phospholipids from the cell membrane to form inositol-1,4,5-triphosphate (IP3), which triggers calcium release from the endoplasmic reticulum (Berridge, 2016), and diacylglycerol (DAG), which opens TRPC6 to extracellular calcium influx. (Anderson et al., 2013)

Thus the podocyte slit diaphragm represents much more than a mechanical barrier to urinary protein loss, rather a complex symphony of inter-dependant protein interactions balancing multiple cellular processes to dynamically regulate one of the most intricate cellular morphologies seen in nature.

Rho/Rac/Cdc42 GTPase Regulation of Actin Cytoskeleton

Rho/Rac/Cdc42 GTPases are a highly conserved group of proteins within the Ras superfamily which collectively play a major role in the regulation of actin dynamics. (Heasman and Ridley, 2008) Consequently the Rho GTPase pathways are strong candidate pathways for dysregulation in SRNS. For example podocyte specific *Cdc42* knockout mouse models develop foot process effacement and proteinuria consistent with an SRNS phenotype. (Huang et al., 2016, Scott et al., 2012)

Figure 2.5 Schematic of known SRNS genes illustrated by functional association within the glomerular filtration barrier. Genes are displayed in groups determined by common function of their protein products including: Slit diaphragm proteins (green), glomerular basement membrane (GBM) proteins (brown), actin binding proteins (yellow), Rho/Rac/CDC42 GTPase regulators (navy), lysosomal proteins (pale blue), mitochondrial gene products (orange), transcription factors and nucleoporins (aqua) and other cytosolic/membrane proteins (pink). Phenocopies are pictured top right in white. A: actin, T: talin, V: vinculin, P: paxillin. Adapted and updated from (Lovric et al., 2016, Preston et al., 2019)

These GTPases switch from an inactive GDP-bound state and an active GTP-bound state affected by guanine nucleotide exchange factors (GEFs). Active GTPases can then exert their function until they are either (i) inactivated by GTPase activating proteins (GAPs), (ii) sequestered by guanine nucleotide dissociation inhibitors (RhoGDIs), or (iii) undergo ubiquitination induced degradation.(Jaiswal et al., 2013, Murali and Rajalingam, 2014) Variants in a number of genes associated with SRNS have been established to disturb the regulation of these GTPases and thus the regulation of actin dynamics.(Lovric et al., 2016, Preston et al., 2019)(Table 2.4, Figure 2.5)

For example, wild type ARHGDI1 forms a complex with RAC1 and CDC42 reducing their activation and GTPase activity.(Gee et al., 2013) Expression of SRNS patient-derived *ARHGDI1* variants in cultured podocytes demonstrated uncontrolled activation of RAC1 and CDC42 activity and increased podocyte migration which improved with RAC1 inhibitor treatment.(Gee et al., 2013) Similar results were found by another group modelling *ARHGAP24* knockdown podocytes after identifying a family with a dominant variant in this gene.(Akilesh et al., 2011) Variants in *KANK1*, 2 and 4 have also been identified in patients with SRNS.(Gee et al., 2015) In rat glomeruli and cultured human podocytes, KANK2 interacts with ARHGDI1.(Gee et al., 2015) However, knockdown of KANK2 in cultured podocytes *increased* RhoA GTPase activity and reduced podocyte motility, indicating a mechanism independent of ARHGDI1.(Gee et al., 2015) A series of six rare, novel, SRNS genes (*ITSN1*, *ITSN2*, *MAGI2*, *TSN2*, *DLC1* and *CDK20*) characterised across 17 unrelated pedigrees affected by steroid sensitive NS (SSNS) and SRNS was recently published by Ashraf and colleagues (2018). In this report, variants in *ITSN1* and *ITSN2* expressed in HEK293 cells or human podocytes demonstrated reduced CDC42 activation compared to wild type vectors. (Ashraf et al., 2018) Podocyte cultures were examined for filopodia extension as an assay of CDC42 associated actin dynamics and were noted to be absent in *ITSN1/2* mutant transfected cultures.(Ashraf et al., 2018, McGavin et al., 2001) The same report demonstrated interaction between MAGI2, TSN2, DLC1 and CDK20 in the GAP regulation of Rho/Rac/CDC42 GTPases.(Ashraf et al., 2018) Using overexpression and knockdown studies for all four genes in various cell cultures, they demonstrated a disturbance in and GTPase activity and podocyte migration rate.(Ashraf et al., 2018)

Dominant variants in *ACTN4* are associated with adult onset FSGS.(Kaplan et al., 2000) *ACTN4* encodes an actin cross linking protein, α -ACTININ 4 which bundles actin fibres and links the actin cytoskeleton to integrins and vinculin.(Akchurin and Reidy, 2015, Weins et al., 2005) Mutant proteins appear to have increased affinity for actin, over-stabilising the cytoskeleton and preventing remodelling and sprouting of actin projections.(Kaplan et al., 2000, Weins et al., 2005, Michaud et al., 2006) Another actin binding protein associated with childhood onset SRNS is MYO1E, a non-muscle myosin.(Mele et al., 2011) These ATPase driven, actin-dependent myosin motors possess actin, calmodulin and cargo binding sites, playing a role in actin reorganisation, intracellular transport and cell signalling.(Krendel et al., 2009, Bi et al., 2013)

Interactions with the Glomerular Basement Membrane

A series of variants in genes encoding laminins and integrins have been linked to SRNS (Kambham et al., 2000, Has et al., 2012, Braun et al., 2019, Zenker et al., 2004), advocating that interaction with the GBM is critical for normal podocyte function. Laminin-521 is the dominant laminin heterotrimer in the mature GBM, composed of $\alpha5\beta2\gamma1$ proteins, and possesses protein interaction domains with many GBM components.(Chew and Lennon, 2018) The LG domain of the LAMA5 (encoding laminin $\alpha5$) subunit binds to $\alpha3\beta1$ integrin and dystroglycan expressed on the apical surface of the podocyte.(Chew and Lennon, 2018) Integrin $\alpha3\beta1$ then forms part of adhesion complexes which interact with the actin cytoskeleton, demonstrating that sound adhesion of the podocyte to the GBM also contributes to actin dynamics.(Akchurin and Reidy, 2015) Recessive variants in both *LAMA5* and *LAMB2* (encoding the $\alpha5$ and $\beta2$ subunits) have been described in patient with SRNS.(Braun et al., 2019, Hasselbacher et al., 2006) Studies of *Lamb2*^{-/-} knockout mice have noted proteinuria prior to the development of GBM or podocyte abnormalities, raising the possibility of disease mechanisms extrinsic to the glomerular filtration barrier.(Jarad et al., 2006) No functional modelling of hypomorphic *LAMB2* or *LAMA5* alleles is published. GBM collagen components COL4A3, COL4A4 and COL4A5 are associated with Alport syndrome and also frequently manifest with proteinuria and FSGS on a histological level.(Zhu et al., 2018, Zhang et al., 2019, Papazachariou et al., 2017, Deltas et al., 2015) The precise molecular mechanism by which collagen deficiencies in the GBM disturb podocyte biology are not well understood but an impairment in podocyte-matrix adhesion seems likely.

Other Genotypes and Proposed Pathways

A series of pathogenic variants in genes encoding proteins involved in coenzyme Q10 (CoQ10) biosynthesis have been described, including *MTTL1*, *PDSS2*, *COQ2*, *COQ6* and *ADCK4*.(Yorifuji et al., 1996, Lopez et al., 2006, Heeringa et al., 2011, Diomedici-Camassei et al., 2007, Starr et al., 2018, Ashraf et al., 2013) CoQ10 is a mitochondrial free-radical scavenger of toxic reactive oxygen species and a cofactor in mitochondrial ATP generation by the respiratory chain enzymes. Knockdown of *COQ6* in human podocytes and zebrafish led to increased apoptosis, rescued by CoQ10 supplementation, supporting a direct toxicity effect.(Heeringa et al., 2011) However *ADCK4* knockdown in podocytes led to impaired migration, an assay well validated in other classes of SRNS genotypes.(Ashraf et al., 2013) Actin polymerisation requires ATP so it is possible mitochondrial SRNS gene variants retard actin remodelling by ATP deficiency.

Other rare variants in genes coding proteins associated with lysosomes, transcription factors, nucleoporins and other cytosolic or membrane pathways have been described which are summarised in Figure 2.5 and Table 2.4. For a number of these genes a genotype-phenotype association has been established on grounds of segregation alone (Ozaltin et al., 2011, Thong et al., 2013, Agarwal et al., 2006, Esposito et al., 2013) without a direct molecular link to regulation of actin dynamics. Others have recapitulated foot process effacement and proteinuria in mutant mouse models.(Braun et al., 2019)

As more genes and their mechanisms are discovered, interactions between the various groups of proteins and pathways are becoming evident. For example ANLN binds CD2AP and may play a role in facilitating signal transduction from the slit diaphragm to the actin cytoskeleton.(Schwarz et al., 2001, Gbadegesin et al., 2014) Another example is IQGAP1 which was found by immunoprecipitation to interact with many slit diaphragm components including nephrin, podocin, MAGI1, CD2AP, NCK1/2, podocalyxin, ACTN4(Rigothier et al., 2012, Lehtonen et al., 2005) and PLCE1. (Hinkes et al., 2006) IQGAP proteins share a number of functions with non-muscle myosins including calcium/calmodulin binding and signalling and regulation of the actin cytoskeleton by interaction with Rac and CDC42 GTPases.(Briggs and Sacks, 2003, Lehtonen et al., 2005, Mateer et al., 2003) Further examples include actin binding protein

MYO1E interaction with cell junction protein ZO1 (Bi et al., 2013) and interaction between ACTN4 and membrane integrins.(Dandapani et al., 2007)

It is important to acknowledge that nephrotic range proteinuria is not solely the manifestation of glomerular disease and a number of genetic causes of proteinuria can act as phenocopies. (Figure 2.5 and Table 2.4)

Genotype Phenotype Correlation

Like many genetic diseases, SRNS is usually phenotypically categorised by the age of onset of proteinuria. Congenital nephrotic syndrome (CNS) has classically described the syndrome of profound neonatal proteinuria and rapid progression to ESRD due to variants in *NPHS1*, one of the first SRNS genes discovered with two specific alleles highly prevalent in Finland (hence the term ‘Finnish Type CNS’).(Kestila et al., 1998) The definition of CNS now broadly applies to children diagnosed under the age of three months. Up to 85% of patients under 3 months of age are due to variants in *NPHS1*, *NPHS2*, *WT1* and *LAMB2*.(Hinkes et al., 2007) Variants in *PLCE1*, *ARHGDI1*, *MAGI2* and *COQ2* have also been demonstrated to contribute significantly to disease burden in this age group.(McCarthy et al., 2013, Sadowski et al., 2015, Gee et al., 2013, Ashraf et al., 2018, Starr et al., 2018)

Beyond this age group, genotype-phenotype association becomes more variable. The age of onset of proteinuria is unsurprisingly governed by both the disturbance of the variant on the protein function, and the dispensability of the protein in the normal homeostasis of podocytes. In older infants and young children, variants in *NPHS2* are most common.(Bierzynska et al., 2017, Santin et al., 2011) Hypomorphic variants in *NPHS1* are described in both children and adults.(Philippe et al., 2008, Santin et al., 2009) The same phenomenon is observed in *LAMB2* variants where highly deleterious variants give rise to Pierson syndrome whereas missense variants manifest as isolated nephrotic syndrome.(Hasselbacher et al., 2006)

Dominant genotypes are generally more likely to cause adult onset phenotypes, whereas recessive phenotypes have higher representation in paediatric disease. Dominant and recessive phenotypes have been proposed within the same genotype. *CD2AP* related

disease has been described in both heterozygous carriers (Gigante et al., 2011) and one infant with SRNS.(Lowik et al., 2007) Whilst autosomal dominant variants in *LAMA5* were first associated with SRNS,(Chatterjee et al., 2013, Gast et al., 2016) subsequent identification of multiple autosomal recessive carriers and lack of phenotype in heterozygous mice (Miner and Li, 2000) have suggested a recessive mode of inheritance.(Braun et al., 2019) Despite the classical X-linked inheritance of *COL4A5* variants and recessive inheritance pattern of *COL4A3* and *COL4A4* variants, the persistence of microscopic haematuria in individuals with heterozygous carriage of any of these genes reflected a dominant phenotype.(Savige et al., 2019) Once termed ‘benign familial haematuria’ a proportion of these patients will develop a more fulminant phenotype.(Fallerini et al., 2014, Fallerini et al., 2017)

Treatments of SNRS are limited

Whilst non-genetic forms of nephrotic syndrome can be effectively treated with immunosuppressive therapy, this is broadly understood to be ineffective for genetic forms of SRNS.(Ruf et al., 2004, Hinkes et al., 2007, Giglio et al., 2015) This is especially true of congenital (<3 months old) and infantile (<12 months old) onset SRNS, which illustrates the important role for genetic testing in establishing those patients where immunosuppressive treatment represents risk without benefit.(Hinkes et al., 2007) In contrast, *PLCE1*, *EMP2* and *LAMA5* variants have documented cases of steroid sensitivity.(Gee et al., 2014a, Braun et al., 2019, Hinkes et al., 2006) Additionally, select patients with *WT1*, *PLCE1* and *LAMA5* variants have demonstrated remission with cyclosporine.(Braun et al., 2019, Hinkes et al., 2006, Gellermann et al., 2010) A number of recently discovered variants have demonstrated partial to complete response to various immunosuppressive therapies.(Ashraf et al., 2018, Gee et al., 2014a) Calcineurin inhibitors have been well characterised for their immunosuppressive effect on T cells, but they are also able to effect a stabilisation of the actin cytoskeleton through improved control of Rho GTPase pathway, a feature that may well benefit patients with genetic variants that produce with Rho GTPase disturbances.(Faul et al., 2008) Variants in *CDK20*, *DLC1*, *ITSN2*, *ITSN2*, *EMP2*, *TNS2* and *MAGI2* are reported to display corticosteroid sensitivity.(Gee et al., 2014a, Braun et al., 2019, Ashraf et al., 2018) This challenges the previously held dogma that steroid sensitive nephrotic syndrome patients are unlikely to benefit from genetic testing, a conundrum that remains unresolved for

many clinical centres, given the higher frequency of SSNS and the expense of genomic sequencing.

For patients with variants in genes involved in the synthesis of CoQ10, supplementation with CoQ10 has been associated with improvement in proteinuria.(Heeringa et al., 2011, Ashraf et al., 2013, Diomedi-Camassei et al., 2007, Starr et al., 2018) Whilst it has not been demonstrated to improve proteinuria, supplementation of vitamin B12 in patients with *CUBN* variants is recommended, as this gene product is involved in the intestinal absorption of this nutrient and deficiency can give rise to serious haematological and neurological sequelae.(Ovunc et al., 2011)

New treatments for nephrotic syndrome are being described in pre-clinical research models. For example, a report by Zhou et al (2017) links increased TRPC5 translocation to the podocyte cell membrane to FSGS disease progression in ATIG transgenic rats. They go on to identify a selective TRPC5 inhibitor AC1903 which improved proteinuria and podocyte loss.(Zhou et al., 2017) Because membrane TRPC5 translocation is upregulated by activated Rac-1, genotypes implicated in dysregulation of the Rho/Rac/Cdc42 GTPase pathway may stand to benefit from this therapy. In another example, 2D podocyte cultures expressing patient-derived podocin variants treated with endoplasmic reticulum (ER) chaperones have improved delivery of ER-retained podocin to the cell membrane.(Ohashi et al., 2003, Roselli et al., 2004) Indeed, allelic variants within a number of genotypes have demonstrated ER retention and activation of the unfolded protein response, with the potential to respond to this brand of chaperone treatment.(Cybulsky et al., 2009, Liu et al., 2001, Chen et al., 2013, He et al., 2011)

Gee et al (2013) treated *Arghria*^{-/-} morpholino knockdown zebrafish with Rac1 inhibitors and a repurposed mineralocorticoid antagonist eplerenone based on the observation of increased Rac1 and mineralocorticoid receptor dependent signalling. They observed a 16-23% reduction in oedema suggesting eplerenone may be a candidate therapy of partial benefit for this genotype.(Gee et al., 2013)

Like many inherited kidney diseases, NPHP and SRNS are both genetic conditions without any targeted therapies in clinical use, but with a number of preliminary therapies

which have been established using animal models. Human kidney organoids represent an opportunity to use a 3D, human, renal, cellular platform for the expedited validation and personalised therapeutic screening of novel therapeutic compounds such as these.

2.5 The directed differentiation of pluripotent stem cells to kidney organoids

2.5.1 Induced pluripotent stem cells (iPSC) can be reprogrammed from somatic cells.

The discovery that skin mature fibroblasts could be reprogrammed to a pluripotent state by the forced, transient expression of key pluripotency genes has revolutionised the field of stem cell research.(Takahashi et al., 2007) Prior to this, stem cell research was performed in murine ESCs or in human ESCs (hESC) obtained from unused human embryos, which became an ethically contentious issue.(McLaren, 2001) iPSC are capable of rapid and extensive self-renewal under appropriate culture conditions. They are also theoretically capable of differentiation to any cell type in the body. Indeed, following injection of stem cells into immunodeficient mice, the formation of a teratoma containing tissues derived from all three germ layers is considered a gold standard assay of pluripotency.(Hentze et al., 2009) The ability to reprogram iPSC from an individual patient's own somatic cells is therefore an approach which overcomes these ethical challenges and opens the door to the field of personalised research and regenerative medicine through directed differentiation of iPSC to various cell types and organoids.

Organoids are small, self-organising, *in vitro* micro-tissues derived from stem cells, which resemble the cell types and structure of the *in vivo* organ.(Lancaster and Knoblich, 2014) The common principle of organoid differentiation protocols is to accurately reproduce the signalling cues that would be experienced by the cell during the development of the *in vivo* organ. Various organoid protocols have established success using this approach, including brain(Lancaster et al., 2013), heart(Giacomelli et al., 2017), liver(Wu et al., 2019a), stomach and intestine(McCracken et al., 2014, Spence et al., 2011)

As outlined above, the kidney contains over 25 different specialised cell types arranged in a complex tissue architecture, performing a variety of highly coordinated functions. Additionally, the nephron is uniquely derived from two different embryologic progenitors. For these reasons the *in vitro* differentiation of kidney from iPSC represents

significant challenges. A number of differentiation protocols have been published for the directed differentiation of kidney organoids,(Morizane et al., 2015, Takasato et al., 2014, Takasato et al., 2015, Taguchi et al., 2014, Freedman et al., 2015) all following the premise of recapitulating in vivo kidney development, much of which has been learned from the study of animals.

During embryogenesis, a continuous sequence of anatomical structures develop under the influence of growth factor signals (also known as morphogens). Each individual cell will experience a varying magnitude and duration of exposure to various morphogens based on their anatomical location as the embryo develops, altering that cell's gene expression and consequently driving its eventual cell fate. Research characterising these developmental pathways has been conducted primarily on non-human animal models and more recently using mouse embryonic and hESC and iPSC models. The following sections detail what is known about mammalian kidney developmental and how this has informed the successful differentiation protocol for kidney organoids.

2.5.2 *Development of the Mammalian Kidney*

All cells making up the mature organs in mammals derive from the *inner cell mass* (ICM), a collection of pluripotent stem cells capable of infinite self-renewal and differentiation into any mature somatic cell. The path to kidney involves cell progression from ICM through posterior *primitive streak* (PS) and *intermediate mesoderm* (IM). The anterior IM gives rise to the *nephric duct*, from which the *ureteric bud* (UB) develops. The posterior IM gives rise to the *metanephric mesenchyme* (MM), the nephron progenitor cell population. The UB invades the MM and undergoes repetitive bifurcation (called branching morphogenesis) to form the tree-like collecting duct structure of the kidney. The MM condenses to form a *cap mesenchyme* (CM) around each tip of the expanding ureteric tree. Reciprocal signalling interactions between the UB and CM drive and synchronise (i) the dichotomous branching of the ureteric tree, (ii) the expansion and maintenance of the CM and (iii) the differentiation of CM cells into *renal vesicles*, which go on to form elongating nephron structures patterned by morphogen gradients within the kidney.(Lindstrom et al., 2014, Takasato and Little, 2015, Little et al., 2016, Little and McMahon, 2012, Costantini and Kopan, 2010) The ureteric tree expands from the centre

Figure 2.6 Development of the mammalian kidney

Schematic diagram detailing the development of the mammalian kidney starting from the posterior primitive streak (PPS) of the gastrulating embryo, from which the mesoderm arises. The intermediate mesoderm (IM) arises between lateral plate and paraxial mesoderm. The IM patterns into anterior (green) and posterior (orange) intermediate mesoderm. The anterior IM gives rise to the nephric duct (ND) which extends along the embryo. The metanephric mesenchyme (MM) forms near the tail bud and the ureteric bud invaginates the MM from the ND at its distal end. The UB forms a dichotomous branching tree of ureteric epithelium (UE) within the MM. Kidney development is controlled by reciprocal signalling between the UE and cap mesenchyme (CM) and Wnt signals from the tips of the ureteric tree promote differentiation of the CM to renal vesicles (RV) which develop into comma shaped bodies and then S shaped bodies (SSB) on their way to develop into nephrons.

. (Reprinted by permission from Springer Nature: Little MH et al, Recapitulating Development to Generate Kidney Organoids Culture In: Organ Regeneration Based on Developmental Biology, Ed. Takashi Springer, Singapore, Copyright 2017)

of the developing organ, pushing the uncommitted CM to the periphery and giving rise to the *nephrogenic zone*. By 36 weeks of human gestation (and shortly after birth in mouse) all nephron progenitor cells are committed to nephron formation and the nephron progenitor pool is extinguished.(Hinchliffe et al., 1991, Ryan et al., 2018) Therefore, in humans, no further nephron units can be generated to replace those diseased or damaged during post-natal life. Individual nephron endowment varies between 0.2 and 2.7 x 10⁶ nephrons per person and is positively correlated with birth weight and gestational age.(Keller et al., 2003, Hughson et al., 2003, Hoy et al., 2003, McNamara et al., 2008)

Posterior primitive streak develops and patterns by the influence of opposing BMP/Nodal morphogen gradients and Wnt signals.

Cells that give rise to the mature kidney arise from the primitive streak (PS), which develops on day 15 of human embryo development as a proliferation and ingression of cells from the epiblast into the dorsal midline of the caudal end of the embryonic disc, undergoing epithelial to mesenchymal transition (EMT). The specification of the PS to form on the posterior aspect of the epiblast occurs via expression of Nodal antagonists *Cer1* and *Lefty1* from the distal visceral endoderm and production of Wnt3 antagonist *Dkk1* from the anterior visceral endoderm.(Yamamoto et al., 2004) Both Nodal mutant (Conlon et al., 1994) and Wnt3 mutant mouse embryos (Barrow et al., 2007) fail to develop PS. Formation of the PS both heralds the beginning of gastrulation (the formation of a trilaminar embryonic disc: endoderm, mesoderm and ectoderm) and defines the left-right, dorsal-ventral and cranio-caudal axes of the embryo.

Opposing gradients of BMP and Nodal/Activin signalling pattern the PS such that anterior structures (exposed to dominant Nodal/Activin signalling) give rise to definitive endoderm (alimentary canal, liver, pancreas, lungs, urinary bladder) whereas more posterior structures experience increasingly dominant BMP4 signalling resulting in mesodermal fate (kidneys, lower urinary tract, gonad musculoskeletal system, heart, blood, spleen).(Robb and Tam, 2004, Tam and Loebel, 2007, Sumi et al., 2008, Nostro et al., 2008) BMP4 signalling is strongest in the posterior PS as it is produced by the proximal embryonic ectoderm. It drives Wnt/ β -catenin signalling via *Wnt3* expression which leads to the co-expression of posterior PS markers *Mixl1*, *Brachyury (T)* and *Kdr*.(Ben-Haim et al., 2006) *Bmp4*^{-/-} null mice and BMP receptor mutant mice fail to form

posterior PS or its derivatives indicating BMP4 is essential for mesodermal development.(Winnier et al., 1995, Beppu et al., 2000) Additionally, brief treatment of hESC cultures with BMP4 alone is sufficient to derive mesodermal structures. (Zhang et al., 2008)

The anterior primitive streak produces BMP4 antagonist (*Noggin*) allowing dominance of Nodal signalling which, in concert with Wnt/ β -catenin signalling, leads to comparatively higher *Mixl1* expression in the anterior IM, expressing *Sox17*, *Eomes* and *Foxa2*.(Funa et al., 2015, Sumi et al., 2008) Both Nodal/Activin and BMP signalling pathways act on a *Mixl1* promoter by generating different complexes of phosphorylated Smad proteins and FoxH transcription factors.(Hart et al., 2005, Attisano and Wrana, 2002, Massague et al., 2005, Funa et al., 2015) Whilst complete Nodal knockout leads to failure of the PS to form(Conlon et al., 1994), progressive attenuation of nodal signalling leads to a proportional loss of the more anteriorly derived mesodermal structures within the primitive streak (eg. axial and paraxial mesoderm) supporting the phenomenon of graded exposure to Nodal determining anterior mesodermal and definitive endodermal fate.(Vincent et al., 2003)

Patterning of the intermediate mesoderm by intermediate BMP4/Nodal gradients and FGF signalling

Patterning of the mesoderm also occurs along a mediolateral plane according to growth factor gradients. IM is characterised by co-expression of *Osr1*, *Lhx1* and *Pax2/8* in animal and hESC models.(James et al., 2006, Bouchard et al., 2002, Tsang et al., 2000) *BMP4* signalling remains strongest dorsolaterally, and is countered by its antagonist *Noggin* produced by the axial and paraxial mesoderm and spinal cord.(Wijgerde et al., 2005) The IM arises between the *BMP4* dominant lateral plate mesoderm and the *Noggin* dominant paraxial mesoderm under the added influence of FGF9 expression observed in the paraxial and IM.(Colvin et al., 1999, James and Schultheiss, 2003, Takasato et al., 2014) The paraxial mesoderm also produces Nodal inhibitor *Cer1* which tempers Nodal signalling along this axis, without which, the IM is noted to expand.(Fleming et al., 2013)

The nephric duct arises in the anterior mesoderm due to Pax2/8 and LHX1 Transcription

The nephric duct (also known as the Wolffian, pronephric or mesonephric duct) arises by mesenchymal-to-epithelial transition from the anterior aspect of the IM, and can be identified by co-expression of *Pax2*, *Lhx1*, *Ret*, *Gata3* and *Hoxb7* among others.(Little and McMahon, 2012) *Lhx1* null mice exhibit reduced *Pax2* expression, disrupted IM differentiation and underdeveloped nephric duct structures(Tsang et al., 2000) with another study finding absence of kidney and gonads.(Shawlot and Behringer, 1995) Expression of *Pax2* or *Pax8* transcriptional regulators has been demonstrated in mouse models to be essential for nephric duct development (Bouchard et al., 2002) and a promotor of *Gata3* expression.(Grote et al., 2006) *Gata3* is a transcription factor expressed widely in the developing genitourinary tract (GUDMAP), *Gata3* null mice demonstrate abnormal nephric duct development and caudal extension.(Grote et al., 2006)

Removal of the BMP4 producing surface ectoderm from chick embryos hampered nephric duct development and nephrogenesis which was rescued by preimplanting BMP4 coated beads suggesting BMP4 remains active and important within the anterior IM for nephric duct development.(Obara-Ishihara et al., 1999) The absence of nephric ducts in retinaldehyde dehydrogenase null mice suggests retinoic acid production from medial mesodermal structures is also important in nephric duct development.(Niederreither et al., 1999)

In human kidney development, two pairs of primitive, transient excretory organs arise from interaction between the nephric duct and nephric cord mesenchyme: the pronephros and mesonephros.(Ranghini and Dressler, 2015) Around the 5th week of human gestation, the MM interacts with UB to form the definitive kidney (the metanephros), after which the pronephros and mesonephros degenerate along with the associated regions of the nephric ducts.(Takasato and Little, 2015)

Induction of the metanephros by reciprocal signalling between the ureteric bud and metanephric mesenchyme

Hox11 gene family expression within the posterior IM has been demonstrated to define MM from the more anterior mesonephric structure by transcribing proteins which form

complexes with *Pax2* and *Eya1*, driving expression of glial-derived neurotrophic factor (*Gdnf*) and *Six2* within the MM.(Gong et al., 2007, Mugford et al., 2008)

The formation of the metanephros is initiated by the response of the nephric duct to *Gdnf* produced by the MM, which binds to the *Ret/Gfr α 1* receptor on nephric duct cells. In response to the *Gdnf* signal, cells expressing higher levels of *RET/GFR α 1* receptor concentrate at the site of the eventual outgrowth of the UB towards the *Gdnf* signal.(Chi et al., 2009, Costantini and Kopan, 2010) *Gdnf/Ret* signalling also upregulates *RET/GFR α 1* receptor expression creating a positive feedback cascade of *Ret* receptor expression and UB cell proliferation towards the *Gdnf* source.(Pepicelli et al., 1997) It also increases *Wnt11* expression which serves to upregulate *Gdnf* expression from within the MM and maintain the CM during kidney development.(Majumdar et al., 2003) Other downstream signals and targets of *Gdnf/Ret* signalling include *Erk/Mapk* and *Pi3k/Akt* signalling pathways which influence cell proliferation, migration and ultimately contribute to a bifurcating pattern of branching morphogenesis of the UB within the MM. (reviewed in (Costantini and Kopan, 2010, Little and McMahon, 2012)) Thus, *Ret*+ ureteric tip cells ultimately give rise to the entire ureteric tree. Indeed, variants in *GDNF/RET/GFR α 1* are found in human patients with renal agenesis or CAKUT(Chatterjee et al., 2012, Davis et al., 2014) and complete loss of *Gdnf*, *Ret* or *Gfr α 1* expression in mice leads to foetal death from renal agenesis.(Jain, 2009)

Nephrogenesis is initiated within CM by Wnt signals from the UB

The MM condenses around the tips of the branching ureteric tree forming the CM. The CM represents the nephron progenitor cell population of the developing kidney giving rise to all epithelial segments of the nephron from glomerulus to early CD. The tightly regulated reciprocal signalling between the CM and ureteric tree results in expansion of the *nephrogenic zone* outwards from the original nucleus of the metanephros confining nephrogenesis to the surface of the developing organ. As the nephrogenic zone moves radially outwards, it leaves behind nephrons which undergo further patterning and development.

CM cells move dynamically within the cap in response to signals from the ureteric tip which support self-renewal and expansion of the nephron progenitor population.(Lawlor

et al., 2019) The CM population are specified by expression of *Six2* and *Cited1*.(Boyle et al., 2008, Kobayashi et al., 2008) *Six2*+*Cited1*+ cells represent the committed but undifferentiated nephron progenitor population and are maintained and expanded by low levels of canonical Wnt9b, BMP7 and FGF9/20 signalling from the ureteric tip.(Karner et al., 2011, Barak et al., 2012, Muthukrishnan et al., 2015) Whilst Wnt9b is a key signal for cells expressing low levels of *Six2* to initiate nephrogenesis, Wnt9b/ β -catenin signalling in the areas of CM expressing higher levels of *Six2* promotes its maintenance.(Karner et al., 2011) Attenuated FGF9 or FGF20 signalling leads to premature differentiation of the cap mesenchyme and loss of FGF20 altogether leads to renal agenesis in mice and humans.(Barak et al., 2012) Downstream signalling pathways of BMP7 and FGF9 interact to maintain cell cycle progression in nephron progenitor cells.(Muthukrishnan et al., 2015) Increased Wnt9b canonical signalling from the underside of the tip promotes Wnt4 expression which acts to induce subsequent differentiation of renal vesicles by mesenchymal to epithelial transition (MET).(Tanigawa et al., 2011, Burn et al., 2011, Carroll et al., 2005) Of note, and of particular relevance to our kidney organoid protocol, pharmacological treatment of isolated mouse kidney mesenchyme to GSK3 β inhibitors have been demonstrated to initiate nephrogenesis.(Kuure et al., 2007) *Foxd1*+ stroma in the nephrogenic zone, through expression of *Fat4*, also plays an active role both in the preventing excessive expansion of the CM and contributing to the signal that induces CM commitment to nephrogenesis.(Das et al., 2013, Bagherie-Lachidan et al., 2015, Mao et al., 2015)

Patterning of the nephron by canonical Wnt signal gradient

The renal vesicle is an epithelial structure which becomes polarised, develops a lumen, invades the distal end of the ureteric tip (forming a connecting segment) and subsequently elongates away from it.(Bard et al., 2001, Georgas et al., 2009) A differential proximal-distal expression pattern becomes evident within the pretubular aggregate, persisting in the renal vesicle and throughout the ongoing development of the ‘comma shape’ and ‘S-shape’ body.(Mugford et al., 2009, Brunskill et al., 2008, Georgas et al., 2009, Saxen and Sariola, 1987) This observation implies the continued role of the ureteric tip in patterning the nephron beyond the initiation of nephrogenesis. The glomerulus and distal tubule juxtapose and the tubular loop between them extends almost clonally into the medulla from an *Lgr5*+ cell cluster within the medial S-shaped body.(Barker et al., 2012)

Patterning of the nephron continues via a Wnt signalling gradient, strongest at the ureteric tip and progressively decreasing towards the glomerulus.(Kopan et al., 2007, Georgas et al., 2009, Lindstrom et al., 2015) The effect of canonical Wnt signalling on the developing nephron has been demonstrated by experiments exposing embryonic kidney organ cultures of a mouse expressing GFP-tagged beta-catenin to GSK3 β antagonists and canonical Wnt antagonists.(Lindstrom et al., 2015) These experiments elegantly demonstrate higher Wnt signalling gives rise to increased distal tubular structures and inhibition of Wnt signalling more proximal structures.(Lindstrom et al., 2015)

The other signalling pathway well characterised in patterning the proximal nephron is the Notch pathway, with Notch2^{-/-} null mutants generating no proximal tubules or glomeruli and Notch overexpression blocking glomerular expression.(Cheng et al., 2007, Boyle et al., 2011) Inhibition of Notch in the Lindstrom et al study found increased Wnt/ β -catenin signalling and associated loss of proximal cell types. This phenotype was rescued by inhibition of β -catenin signalling suggesting that the role of Notch pathways in nephron patterning may be to antagonise β -catenin signalling.(Lindstrom et al., 2015) This study also found that β -catenin signalling was downregulated in the medial segments of the nephron (which give rise to the elongating loop of Henle).(Lindstrom et al., 2015)

Uncharacterised aspect of the molecular biology determining nephrogenesis and nephron patterning remains are likely to be illuminated by technological advances such as single cell RNA sequencing. Preliminary reports would suggest regionalised segregation and interactive signalling between stromal, ureteric and developing nephron structures.(Thiagarajan et al., 2011, Magella et al., 2018, Combes et al., 2019a, Combes et al., 2019b, Rutledge et al., 2017, Lee et al., 2015)

Cessation of nephrogenesis potential in humans before birth

In mice nephrogenesis continues for a few days into post-natal life, with a gradual reduction in nephron progenitor numbers occurring with each division of the ureteric tree.(Lindstrom et al., 2018a, Combes et al., 2014) In humans nephrogenesis continues until around 36 weeks of gestation (Hinchliffe et al., 1991) at which point a surge of nephrogenesis extinguishes the CM.(Hartman et al., 2007, Rumballe et al., 2011) As a

result, no nephron progenitor population remains to generate new nephrons in the post-natal human that may be lost to disease, injury or aging.

2.5.3 *Directed differentiation of iPSC to kidney organoid.*

A number of groups have published approaches for the directed differentiation of embryonic or induced pluripotent stem cells to a renal end point, be that a specific kidney cell type or multicellular kidney organoid.(Mae et al., 2013, Mae et al., 2018, Taguchi et al., 2014, Taguchi and Nishinakamura, 2017, Lam et al., 2014b, Takasato et al., 2014, Takasato et al., 2016, Takasato et al., 2015, Freedman et al., 2015, Morizane et al., 2015, Imberti et al., 2015, Araoka et al., 2014, Przepiorski et al., 2018) All *in vitro* protocols share a common approach of mimicking the *in vivo* pathway of kidney development from ICM through PPS to IM, MM and putative nephron.

Early protocols were performed starting with either monolayers of stem cells cultured in 2D or embryoid bodies (EB). Kidney regeneration approaches using EB as a start point took their cue from published organoid protocols for blood, pancreas, optic cup, brain and intestinal tract differentiation.(Ng et al., 2005, Micallef et al., 2007, Lancaster et al., 2013, McCracken et al., 2014, Eiraku et al., 2011) Comparable kidney specific end points have been achieved with both strategies, indicating neither is superior.(Wu et al., 2018b)

Canonical Wnt signalling is sufficient to differentiate iPSC to posterior primitive streak.

Most protocols have utilised a small molecule GSK3 β inhibitor CHIR99021 to induce canonical Wnt signalling and pattern iPSC to PPS, assessed by co-expression *MIXL1* (a PS marker) and *T* (more specific to PPS) and reduced expression of *SOX17* (anterior PS).(Lam et al., 2014a, Takasato et al., 2014, Takasato et al., 2016, Takasato et al., 2015, Freedman et al., 2015, Przepiorski et al., 2018) As already discussed, GSK3 β forms part of the β -catenin degradation complex and its inhibition allows for increasing cytosolic β -catenin and subsequent canonical Wnt signalling. Whilst the dose and duration of CHIR99021 varies between protocols, this is most likely a product of the inherent variability of necessary culture conditions between different iPSC lines used by different laboratories. Many groups have incorporated Activin A and BMP4 into their protocols, in an attempt to better specify and pattern PPS.(Taguchi et al., 2014, Araoka et al., 2014, Mae et al., 2013) This is not an unreasonable approach given the role of Nodal signalling

in PPS development and the opposing gradients of BMP4 and Nodal signalling establishing its anteroposterior patterning (described in Section 2.5.2). Indeed using a *MIXL1-GFP* reporter and qPCR for *T* and *SOX17* expression, Takasato et al described that co-treatment with high BMP4 (30ng/mL) and low Activin A (10ng/mL) or 7 μ M CHIR99021 were equally capable of differentiating PPS.(Takasato et al., 2014) Finally, Morizane added Noggin (a BMP4 antagonist) to CHIR99021 PPS induction to reduce expression of *FOXF1* (lateral plate mesoderm) in their PPS culture.(Morizane et al., 2015)

Induction of the intermediate mesoderm by FGF9 signalling.

Attempting to recapitulate the many multidimensional morphogen gradients in the increasingly complex embryo has yielded variety of published approaches for progressing kidney organoid cultures from PPS to IM. Freedman et al (2015) add no further growth factors and simply cultured a monolayer of cells in Roswell Park Memorial Institute (RPMI1640) basal media with B27 supplement. Areas of the culture that start to develop tubular structures are then dissected from the primary culture and cultured further.(Freedman et al., 2015) Whilst it is likely that this method gives rise to significantly more off-target differentiation in the primary monolayer, it has proven a remarkably straightforward and reproducible approach. At the other end of the spectrum, Taguchi et al (2014) describe an intricate protocol informed by a meticulous *in vivo* lineage tracing approach in mice. This protocol patterns iPSC to a posteriorised nascent mesoderm with CHIR99021 and BMP4 and then IM with by addition of retinoic acid and Activin A.(Taguchi et al., 2014)

Both Morizane et al (2015) and Takasato et al (2015) give consideration to the *in vivo* timing of cellular migration from the PS, and how this temporally determined exposure to its morphogen signalling affects mesodermal patterning along the anteroposterior axis. Cells migrating earlier will encounter greater FGF9 and RA signalling and form the anterior IM and subsequently UB structures. Cells migrating later will not move as far caudally and therefore experience more Wnt signalling than FGF9 or RA signalling, fating posterior IM and subsequent MM progenitors. Having screened a large number of candidate growth factors (including FGF9 up to a concentration of 100ng/mL), Morizane et al (2015) targeted posterior IM by treating with Activin A to arrive at

Author, Year	Culture Method	Derivation of Intermediate Mesoderm (IM) via Posterior Primitive Streak (PPS)	Derivation of Metanephric Mesenchyme (MM) and/or Ureteric Bud (UB)	Endpoints and markers by immunofluorescence						Notes
				Glom	PCT	DT	CD	Endo	Stroma	
Mae et al. 2013	Monolayer	<i>PPS</i> : 3 days CHIR99021 + Activin A <i>IM</i> : 8 days CHIR99021 + BMP7	<i>MM</i> : 7 days CHIR99021, BMP7	+	+					Generated an OSR1-GFP reporter line to enable high throughput growth factors screening for IM induction.
Taguchi et al, 2014	Embryoid Body	<i>Epiblast</i> : 2 days Activin A <i>PPS</i> : 2 days CHIR99021, BMP4 <i>Posterior nascent mesoderm</i> : 4 days CHIR99021, BMP4 <i>Posterior IM</i> : 2 days Activin A, BMP4, CHIR99021, RA	<i>MM</i> : 3 days CHIR99021, FGF9	+	+	+				MM was derived under fully defined conditions but culture of organoid end points was by culture with dorsal spinal cord.
Lam et al, 2014	Monolayer	<i>PPS</i> : 2 days CHIR99021 <i>IM</i> : 4 days FGF2 + RA	<i>MM</i> : 3 days FGF9 + Activin A		+					IM differentiated into LTL+, N-cadherin+ PCT cells with removal of FGF2 and RA and 1 day CHIR99021.
Takasato et al, 2014	Monolayer	<i>PS</i> : 2 days CHIR99021 <i>IM</i> : 4 days FGF9 + Heparin	<i>MM and UB</i> : 6 days FGF9 + Heparin then 6 days no growth factors.	+	+	+	+			Early podocytes colocalising WT1+ and synaptodin+ with PCR evidence for upregulation of podocyte genes.
Araoka et al, 2014	Monolayer	<i>PPS</i> : 2 days CHIR99021 + Activin A <i>IM</i> : 4 days AM580 or TTNPB	<i>MM and UB</i> : 8 days Wnt3a + BMP7	+	+		+?			Also found CHIR99021 alone can give rise to PPS. TTNPB protocol was utilised for the differentiation of end point cultures.
Imberti et al, 2015	Monolayer	<i>PPS/IM</i> : 6 days RA + PI3K inh + RhoA inh + 2 days activin A	<i>MM</i> : FGF2 + BMP7 + GDNF	+	+					Integration of human renal progenitors into cisplatin injured mouse nephrons was observed.
Morizane et al, 2015	Monolayer then 3D	<i>Late PS</i> : 4 days CHIR99021 ± noggin <i>Posterior IM</i> : 3 days activin A	<i>MM</i> : 2 days FGF9 <i>Self-organising nephrons</i> : 2 days FGF9 + CHIR99021 then 3 days FGF9 then no growth factors.	+	+	+			*	3D culture performed by replating cells on day 10 to ultra-low-attachment, round bottom 96-well plates and in suspension culture.
Freedman et al, 2015	Spheroid	<i>Epiblast spheroid</i> : 2 days sandwiched between Matrigel in mTeSR1 medium <i>Mesoderm</i> : 1.5days CHIR99021	<i>Self-organising nephrons</i> : 12 days B27 supplement	+	+	+		+		Generated epiblast spheroids in Matrigel sandwich culture, prior to differentiation. CD31+/ <i>v</i> WF+ endothelium also present.
Takasato et al, 2015	Monolayer then 3D	<i>PPS</i> : 4 days CHIR99021 <i>Ant and Post IM</i> : 3d FGF9 + Heparin	<i>Organoid</i> : 1 hour CHIR99021, then 5 days FGF9 + Heparin, then 7 days no growth factors.	+	+	+	+	+	+	First report of endothelial progenitors (CD31+, SOX17+) with lumen formation, observed invading glomeruli.

Table 2.5 Fully defined protocols for the *in vitro* directed differentiation of human iPSC to nephron fate

IM – intermediate mesoderm; PPS – posterior primitive streak; RA – retinoic acid; Glom – glomerular structures; PCT – proximal convoluted tubule; DT – distal tubule; CD – collecting duct; Endo – endothelium, *personal communication. Takashi Springer, Singapore, Copyright 2017)

WT1+/HOXD11+/PAX2-/LHX1- cell population. Takasato et al (2014a) titrated FGF9 with and without Noggin or BMP4 with the goal of achieving a balance of anterior and posterior IM, arriving at a treatment of FGF9 alone at 200ng/mL for 3 days for the iPSC line tested. The addition of heparin is required as FGF9 is a heparin dependent ligand for FGF receptors.(Hecht et al., 1995) This gave rise to a *PAX2+/LHX1+/OSRI+* culture with lowest expression of *TBX6* (paraxial mesoderm) and *FOXF1*.(Takasato et al., 2014) Importantly from a disease modelling perspective, the Takasato protocol illustrates the potential to engineer the relative exposures to CHIR99021 and FGF9 during the monolayer cultures to pattern the regenerated nephrons to more proximal (eg. glomerular structures) or more distal (eg. distal tubular) structures, based on the disease being studied. (Takasato et al., 2015)

3D culture permits self-organisation of nephrons from differentiated cells.

Whilst the spontaneous development of nephron structures has been demonstrated in 2D cultures the field has unquestionably moved in the direction of 3D cultures. Having initially optimised a protocol in 2D (Takasato et al., 2014), Takasato et al (2015) adapted embryonic kidney reaggregation protocols,(Weiss and Taylor, 1960, Unbekandt and Davies, 2010, Saxen and Lehtonen, 1987) dissociating the monolayer culture and reaggregating cells in centrifuged pellets on a transwell membrane.(Figure 2.7) These cultures were given a ‘pulse’ of CHIR99021 for 1 hour as a canonical Wnt stimulus to induce nephrogenesis.(Takasato et al., 2015) They were then treated with FGF9 for a further 5 days followed by withdrawal of all growth factors. (Takasato et al., 2015) Cells within these aggregates self-organised into nephrons representing 4 major segments including NPHS1+ glomeruli, LTL+ proximal tubule, ECAD+ distal tubule and ECAD+/GATA3+ late distal tubule/collecting duct structures.(Takasato et al., 2015)(Figure 2.7) A similar principle of providing a nephrogenic Wnt stimulus was employed by Taguchi et al (2014) co-culturing their MM cultures with mouse embryonic spinal cords. However this may be a dispensable step given the number of protocols successfully differentiating kidney organoids without a nephrogenic Wnt source. (Freedman et al., 2015, Morizane et al., 2015, Przepiorski et al., 2018) Morizane et al deferred dissociation until day 9 when cells had reached MM identity and reaggregated cells by moving the culture to low attachment 96 well U bottom plates.

Figure 2.7 Schematic depiction of the Takasato et al (2015) iPSC kidney organoid differentiation protocol used throughout this thesis. iPSC cells are plated on Matrigel one day prior (D-1) to differentiation in Essential 8. On D0 cells commence culture in basal media treated with CHIR99021 for between 3 and 5 days before switching to FGF9 and its required cofactor heparin. Each individual cell line requires optimisation to establish the correct protocol to guide the cells through posterior primitive streak and intermediate mesodermal fates. On D7 the cell monolayer is dissociated and re-aggregated by centrifugation into pellets which are then cultured on a transwell air-liquid interface. Nephrogenic stimulus is provided by a 1 hour treatment (a 'pulse') of CHIR99021 before continuing FGF9 treatment for 5 days and then withdrawing all growth factors. Cells self-organise into nephron structures as validated by immunofluorescence for NPHS1 (glomeruli, white), LTL (proximal tubule, blue), ECAD (distal tubule, green) and ECAD/GATA3 (collecting duct, green and red). Scale bars 500 μm.

These organoids demonstrated glomeruli, proximal tubules and ECAD⁺ distal tubular structures but lacked a GATA3 positive cell population. Single cell RNA sequencing of these protocols has demonstrated a similar spectrum of cell types, including vascular progenitors (CD31⁺/KDR⁺/PECAM⁺), pericytes (PDGFRA⁺) multiple separable clusters of stroma (MEIS1⁺), and 10-20% of cells representing off-target cell types.(Wu et al., 2018b, Combes et al., 2019b, Subramanian et al., 2019, Phipson et al., 2019)

An increased yield of kidney organoid tissue has been published by two groups utilising suspended culture approaches.(Kumar et al., 2019, Przepiorski et al., 2018) Kumar et al adapted the Takasato et al protocol (2015) into a swirler culture in a 5cm diameter low attachment culture dish, demonstrating an equivalent end product but with 4x greater cell yield.(Kumar et al., 2019) Przepiorski et al (2018) published a similar protocol starting with EB culture and moving to a larger spinner flask. This report substituted Knockout Serum Replacement (KOSR) for expensive recombinant human FGF representing significant cost savings without appreciably altering the quality of the cells derived, but with a higher frequency of spheroids lacking kidney structures.(Przepiorski et al., 2018) The reason why KOSR acted as a reasonable substitute for recombinant FGF2/9 is not clear.

Culture of ureteric epithelium

One controversy pertaining to the Takasato et al (2015) organoid has been whether the ECAD⁺/GATA3⁺ segments genuinely represent a derivative of the UB or, rather an MM derived connecting segment, the region connecting the nephron to the ureteric tree. Contiguous networks of ECAD⁺/GATA3⁺ epithelium are noted in these cultures connecting multiple nephrons.(Little and Combes, 2019, Higgins et al., 2018)(Figure 2.7) *SIX2* lineage tracing suggests that GATA3⁺ cells do not derive from a *SIX2*⁺ MM precursor.(Howden et al., 2019) Finally transplantation of organoids under the murine renal capsule gives rise to tubular maturation and the EM appearance of principle and intercalated cells of CD.(van den Berg et al., 2018) However, the morphogenesis of these ECAD⁺/GATA3⁺ segments is not reminiscent of dichotomous UB branching seen *in vivo*. Additionally, neither bulk RNA nor single cell profiling of kidneys has not identified a cluster of cells expressing ureteric tip markers such as *WNT9B* or *RET*.(Wu et al., 2018b, Combes et al., 2019b, Subramanian et al., 2019, Phipson et al., 2019) It has recently been

established that GATA3 is expressed in the murine connecting segment which is derived from the MM.(Lindstrom et al., 2018c, Georgas et al., 2009, Combes et al., 2019a) This raises the question of which markers are specific for ureteric epithelium (UE) without expression in late distal tubule or the connecting segment. Indeed, a number of traditionally used markers for UE/CD have been demonstrated to be expressed in connecting segment in mice using single cell RNA sequencing.(Combes et al., 2019a) This includes markers such as *Apq2*, *Krt8*, *Krt18* and even *Hoxb7* which has long been utilised as a Cre-driver for flox knockout mouse in mouse collecting duct.

In an attempt to differentiate UB, Xia et al patterned iPSC monolayers to a *T+* PPS using BMP4 and FGF2 for two days, followed by RA, Activin A and BMP2 for another two days to induce an OSR1+/LHX1+/PAX2+/PAX8+/GATA3+ anterior IM.(Xia et al., 2013) Two days after removal of growth factors cells displayed escalating expression of *HOXB7*, *RET*, *GFRA1* and *GDNF* by qPCR with low expression of CM markers *SIX2*, *CITED1* and *SALL1*.(Xia et al., 2013) These cells integrated into aggregate cultures with dissociated mouse kidney to form chimeric ureteric bud structures positive for CK8 and displaying *in vivo* ureteric tip like morphology complete with non-chimeric SIX2+ CM.(Xia et al., 2013) This protocol was replicated in iPSC from patients with ADPKD without demonstration of any disease specific phenotype.(Xia et al., 2013)

Two further reports have since been published describing precise, stepwise protocols, based on an eloquent understanding of mouse nephric duct and UB development, under the premise that to derive true UE requires a separate protocol to that for MM.(Mae et al., 2018, Taguchi and Nishinakamura, 2017) Both used combinations of Activin A, BMP4, CHIR99021, TGF β inhibitors, RA analogues and FGF8 to pattern to anterior IM.(Mae et al., 2018, Taguchi and Nishinakamura, 2017) From this point Taguchi et al (2017) purified their culture by flow cytometry for CXCR4+/KIT+ nephric duct progenitors and were able to induce stunning branching morphology using GDNF. Furthermore, aggregate co-culture with mouse ESC derived nephron progenitors and primary mouse fetal kidney stroma established successful culture of a 'higher order kidney' complete with SIX2+ nephron progenitors and forming nephrons attached to a branching central backbone of ureteric epithelium.(Taguchi and Nishinakamura, 2017) Regrettably, they were unable to recapitulate the protocol using human iPSC. Mae et al (2018) achieved a

greater induction efficiency (~70%) and morphology reminiscent of *in vivo* dichotomous branching GATA3⁺ ureteric tip with RET⁺ tips and CK19⁺ stalks following treatment with GDNF.(Mae et al., 2018)

Thus a number of protocols, all varying in their growth factor treatments and 3D culture strategy broadly appear to arrive at similar end points. This might suggest that self-organisation plays a major role in the final cell fate specifications once guided in the correct direction. An alternative interpretation would be that the high degree of flexibility of these protocols explains the somewhat rudimentary nature of the model in its current form.

Presently, from a disease modelling perspective, a balance needs to be established between precise, highly engineered protocols such as those published by Taguchi et al (2014, 2017) and Mae et al (2018) and the practicality and transferability of the more simplistic Morizane et al (2015) and Takasato et al (2015) protocols. Whilst the latter may derive less mature or precise end products, their simplicity is attractive in the circumstance where multiple iPSC lines will require protocol optimisation. As it was developed within our laboratory and gives rise to more nephron segments than other published protocols, the Takasato et al (2015) protocol will be utilised exclusively throughout this thesis.(Figure 2.7)

Ultimately a protocol will suffice if the model is able to reflect a disease phenotype that is faithful to that seen *in vivo*, is reproducible and can be performed in a timely enough manner to guide a personalised therapeutic management.

2.6 Renal Disease Modelling using Kidney Organoids

2.6.1 Strengths and limitations of iPSC-derived kidney organoids as a disease model.

The opportunity to study complex, multicellular, *in vitro* kidney tissues regenerated from a patient's own cells offers clear advantages to existing disease modelling platforms. However, organoids also have limitations and stand to complement, rather than replace, animal models and 2D cell cultures.

2D vs 3D culture

A clear benefit of organoids as accurate models of *in vivo* kidneys lies in the ability to culture cell types in 3D. This permits physiological cell-cell and cell-ECM interactions more faithful to the *in vivo* circumstance.(Pampaloni et al., 2007) This was acknowledged even prior to the development of organoids. For example, the gene expression profile of melanoma cells in spheroid culture was observed to be closer to primary melanoma tissue than those cultured in 2D.(Ghosh et al., 2005) In another example, human immortalised proximal tubular epithelial cells cultured in a 3D printed tubular lumen exhibit superior cuboidal morphology, brush border density, megalin expression and albumin uptake than in 2D culture even prior to perfusion flow.(Homan et al., 2016) Using an iPSC line expressing a blue fluorescent protein (BFP) inserted at the start codon of the endogenous *MAFB* locus, expression of this key podocyte gene was able to be assayed in real time culture.(Hale et al., 2018) Glomeruli sieved from kidney organoids maintained *MAFB-BFP* expression for up to 4 days in suspension culture, however as soon as they were allowed to settle, *BFP* expression vanished from both the glomeruli and the 2D podocyte monolayer than emanated from them, suggesting rapid dedifferentiation.(Hale et al., 2018) Furthermore, bulk RNA sequencing of isolated organoid glomeruli demonstrated superior expression of numerous key podocyte genes compared to 2D immortalised podocytes.(Hale et al., 2018) This work also demonstrated improved maturation of ECM within 3D glomeruli, with evidence of collagen and laminin switching.(Hale et al., 2018)

The self-organisation of cells into complex tissue structures in kidney organoids provides a perspective on tissue function not seen in 2D cell culture. An example is the podocalyxin knockout organoid published by Freedman et al (2015) where glomeruli formed in the absence of podocalyxin but seemed unable to establish an organised and polarised internal glomerular structure.

Another benefit of 3D organoids is the ability to culture multicellular structures. Whilst not fully characterised, cell-cell crosstalk between different populations is likely to play a role in cell behaviour, disease and development.(Pampaloni et al., 2007) A developmental example is the regulation of the CM expansion by *Foxd1*⁺ stroma in the nephrogenic zone which is co-dependant on *Fat4* expression from the stroma and *Six2* expression from the CM.(Das et al., 2013, Bagherie-Lachidan et al., 2015, Mao et al.,

2015) In NPHP, most research has focused heavily on epithelial dysfunction, however interstitial fibrosis is a key histological feature of this disease that many consider a primary aspect of disease rather than a secondary consequence of epithelial damage and dysfunction.(Slaats et al., 2016, Wynn and Ramalingam, 2012) Additionally, cell microenvironment has been demonstrated to play a key role in cystogenesis of organoid models of ADPKD, with cysts increasing in size when removed from adherent culture.(Czerniecki et al., 2018) Whilst much of the cell-cell cross talk in kidney development and disease is between stromal and epithelial cells, the characterisation of renal stroma in human fetal kidney is in evolution and the ability for kidney organoids to accurately replicate this is also uncharacterised.(Lindstrom et al., 2018a, Little and Combes, 2019) Furthermore, single cell RNA sequencing analysis of kidney organoids has established that they contain a significant component of off-target cell types.(Wu et al., 2018b, Subramanian et al., 2019, Combes et al., 2019b) Characterisation, optimisation and reproducibility of the stromal component of organoids will be critical before any meaningful research can be performed examining ‘fibrosis’ of the organoids as a readout of disease.

Multicellular, *in vitro* culture in three dimensions is not without its disadvantages. Cell culture in 2D is less faithful to the *in vivo* cell context, it is straightforward, cheap and represents minimal technical variability. Whilst the simplicity of 2D cell culture may limit its *in vivo* relevance, the generation of pure unicellular RNA or protein lysates takes seconds to minutes permitting the testing of multiple conditions. In contrast, the isolation of a single cell type from a complex, multicellular organoids requires extended dissociation and technical protocols which take hours to complete. This limits the number of conditions that can be executed simultaneously and introduces technical artefact and variation arising during dissociation and purification.

Renal disease is best studied in renal cellular models

Patient-derived cells, usually skin fibroblasts, have been utilised for decades as surrogate functional genomic models for other less obtainable primary tissues. In the ciliopathy field, there has been a long held assumption that primary cilia (an almost ubiquitous cellular organelle) maintained the same structure and function in all cells.(Wheatley, 1995) However, recent studies have demonstrated subtle differences in the physiology of

cilia in different cells. For example, a study examining *Kif17* (encoding homodimeric kinesin II motor) homozygous mutant zebrafish found morphological differences only in olfactory cilia.(Zhao et al., 2012) In contrast, *Kif3b* (encoding heterotrimeric kinesin-II protein) was obligatory for ciliogenesis, except in photoreceptors and some auditory hair cells.(Zhao et al., 2012) In another example, a mouse expressing mutant *Tctn1* (a ciliary transition zone protein) demonstrated abnormal cilia number and appearance at the embryonic node and neural tube but with undisturbed ciliogenesis in the limb bud and perineural mesenchyme.(Garcia-Gonzalo et al., 2011) Most recently in human iPSC modelling patients with *CEP290* variants, tissue specific ciliogenesis defects were identified in iPSC derived optic cups, but not in skin fibroblasts from patients with Leber's congenital amaurosis.(Shimada et al., 2017) In patients with Joubert syndrome, however, both fibroblasts and iPSC derived optic cups were affected.(Shimada et al., 2017) These studies advocate that modelling of renal disease should ideally be performed using renal tissue, and this represents one of the major strengths of kidney organoids as a functional genomic platform.

The advantages of throughput and scale

Another key advantage of iPSC-derived kidney organoids over other models is the capacity to culture infinite quantities of an individual patient's kidney tissue. Combining microwell plates with robotic culture techniques and machine learning, Czerniecki et al (2018) were able to efficiently optimise a culture protocol for three iPSC lines. Whilst the results between replicate wells were somewhat variable, this represents a notable example of the power of automated liquid handling systems and high content analysers in organoid research. As a disease modelling extension of this approach the same group screened cystogenesis in PKD1 knockout kidney organoids treated with eight candidate compounds.(Czerniecki et al., 2018, Cruz et al., 2017) This led to the discovery of increased cystogenesis in response to treatment with a non-muscle myosin II (NMII) inhibitor, and the subsequent testing of a NMII activator as a candidate novel therapy for ADPKD.(Czerniecki et al., 2018, Helms et al., 2019)

In vivo vs in vitro disease modelling

The murine kidney grows within a physiological, developmental environment with a blood supply and urinary drainage system. Kidney organoids possess vascular progenitors

but *bona fide* blood vessels are not demonstrated to develop within organoids unless they are transplanted into an organism that can vascularise them.(Sharmin et al., 2016, van den Berg et al., 2018, Tanigawa et al., 2018) This has been demonstrated to improve the maturity of the organoids, establish tubular flow and develop the glomerulus for objective assessment of foot process morphology in nephrotic syndrome.(van den Berg et al., 2018, Tanigawa et al., 2018) Theoretically this may also provide the ability to model diseases of the GBM. The act of transplanting an *in vitro* organoid into a mouse, however, regresses a potentially high throughput platform into a more cumbersome, low throughput platform with more limited disease modelling utility, essentially trading higher quality for lower quantity. Accordingly, efforts have been made at *in vitro* vascularisation utilising flow. In a specialised microfluidic culture device, kidney organoids were exposed to fluid flow shear stress, which increased both the vasculature and the transcriptional maturity of the organoid.(Homan et al., 2019) The addition of VEGF increased the volume of blood vessels but reduced the average proximity of the vessels to the epithelial structures, concluding that relying on the endogenous VEGF production from organoid glomeruli was more ideal.(Homan et al., 2019) Whilst glomerular vasculature was observed by EM, the development of a glomerular filtration barrier remained primitive.(Homan et al., 2019) Additionally, there was no convincing evidence of perfusability of the vessels formed.(Homan et al., 2019) A suite of complex bioengineering vascularisation techniques exist to overcome this challenge, including sacrificial inks and microfluidic chips among others.(Grebenyuk and Ranga, 2019) This will remain a critical hurdle for the field to overcome given the importance of the endothelial-podocyte interaction in the modelling of glomerular disease.

Mouse vs human disease models

Animal disease models offer many benefits that organoids cannot fulfil. Firstly, the mouse kidney belongs to a fully functioning organism, allowing interrogation of non-renal phenotype and the study of systemic diseases that are recognised to extrinsically damage the kidneys. Secondly, organoids exhibit technical variation in differentiation end-point including degree of off-target cell populations and nephron patterning, between individual experiments.(Phipson et al., 2019), whilst a naturally developed animal kidney will broadly arrive at the same end-point for any given time.

For the most part, modelling of human derived genotypes in mice gives rise to a similar phenotypic representation.(Hofmeister et al., 2017) However, significant differences in development, anatomy, physiology, gene-ortholog representation and environment limit the direct translation of findings in animal models to clinical practice. To begin with, mouse kidneys are unipapillate and develop much faster (~1 week) than human kidneys (~30 weeks) which are multipapillate.(Little, 2015) Human nephrons demonstrate a capacity to develop away from the branching ureteric tip and insert into other nephrons, usually in the cortex, a process called arcading not seen in mice.(Zhai et al., 2006) Nephrogenesis ceases in humans prior to term gestation but continues in mice until 1-3 days post-natal age.(Hartman et al., 2007, Hinchliffe et al., 1991) These phenomena suggests fundamental differences between the species in the behaviour and relationship between the CM and the ureteric tree.

Transcriptional and anatomical differences in kidney development highlight examples where translation between the species may be limited.(Lindstrom et al., 2018a, Lindstrom et al., 2018b, Lindstrom et al., 2018c) For example, there appears to be a functional redundancy between *SIX1* and *SIX2* within the maintenance of human CM, whereas *Six1* is downregulated in mouse CM and *Six2* is essential for maintenance of the murine CM.(O'Brien et al., 2016) Autosomal dominant *SIX1* variants have a recognised association with branchio-oto-renal (BOR) syndrome in humans and *SIX2* variants have an association with CAKUT. The differential expression profiles of these genes in CM between mouse and human and the lack of functional redundancy between the two genes in mouse has created some confusion with regards to the clinical pathogenicity of *SIX2* variants in human kidney disease.(Combes et al., 2018, Weber et al., 2008, Faguer et al., 2012, Hwang et al., 2014) Multiple attempts to model ARPKD in mice have failed to emulate an early onset polycystic kidney disease, rather an early onset liver disease and variably penetrant polycystic kidney disease manifesting around 3-6 months.(Bakeberg et al., 2011, Woollard et al., 2007, Moser et al., 2005, Williams et al., 2008) The reason for this is not understood but it is likely to involve differential splicing given the gene is so large and transcribes a large number of isoforms.(Ward et al., 2002, Menezes et al., 2004, Nagasawa et al., 2002, Boddu et al., 2014) Another example is autosomal dominant *HNF1B* variants, a common cause of a spectrum of CAKUT in humans(Decramer et al., 2007, Heidet et al., 2010, Clissold et al., 2015), but which only displays a renal phenotype

in mice when homozygote deletions are introduced.(Desgrange et al., 2017, Massa et al., 2013) These examples where mice seem unable to accurately portray a well established human phenotype make human kidney organoids an attractive model for research.

In *Haa0*^{+/-} and *Kynu*^{+/-} mice engineered to model cardiac, vertebral and renal congenital defects thought to be due to antenatal nicotinamide adenine dinucleotide (NAD) deficiency, no phenotype was observed in offspring due to differences in niacin metabolism between mouse and human and a high niacin content of the mouse feed.(Shi et al., 2017) However, offspring of *Haa0* and *Kynu* null mice demonstrated universal fetal mortality, which was effectively rescued by progressive niacin supplementation.(Shi et al., 2017) This represents a fascinating example of how differential interspecies gene-environment interactions can confound functional genomic modelling.

Further to representing a human genotype, iPSC derived from patients with inherited kidney disease can model a patient specific genotype, inclusive of the gene of interest and any other previously unrecognised genetic variants which might also be contributing to the phenotype. Where no variant has been identified, an iPSC derived organoid will contain the correct genetic variant responsible for disease and potentially allow its identification, though no such examples of this retrospective approach have been published.

Whole organoid expression profiling most closely correlates to trimester 1-2 human fetal kidney (Takasato et al., 2015) and maturation effectively arrests following the withdrawal of growth factors.(Phipson et al., 2019) As such, organoids are likely best placed to model renal diseases with an onset of phenotype in childhood, or even antenatally. Whilst a number of adult onset diseases have been modelled in organoids(Dvela-Levitt et al., 2019, Cruz et al., 2017), whether this immaturity will affect or confound the findings of these reports remains unknown. Mouse models, by comparison provide the opportunity to study disease phenotype after much longer periods and with continuing physiological development and subsequent aging of the kidneys and disease.

Ethical considerations

Finally, iPSC reprogramming obviates the ethically controversial need to obtain hESC from discarded, IVF-conceived, human embryos.(Zheng, 2016, Zacharias et al., 2011) However, the use of iPSC cells in research brings with it a new set of ethical considerations. It is essential that when a patient is recruited for iPSC based tissue culture research, that consent processes exist to fully inform that patient of the confidentiality and control they retain over their cells and the information generated by iPSC research, which would be analogous to that they maintain over their clinical medical records.(Lowenthal et al., 2012, Aalto-Setälä et al., 2009) All such research must be overseen by relevant regulatory and ethical review committees.(Lowenthal et al., 2012) Researchers are advised to discuss with donors: (i) the types of experiments their cells and differentiated tissues could be used for (eg. xenotransplantation); (ii) any intention to genetically modify their cells or share cells with other researchers; and (iii) large scale genome sequencing of cells which may discover clinically relevant incidental genomic diagnoses.(Aalto-Setälä et al., 2009, Mallett et al., 2015, Lowenthal et al., 2012) Any clinical human transplantation or reproductive research would require a separate and specific regulatory and ethics committee review and donor consent process.(Aalto-Setälä et al., 2009)

Each class of functional genomic model inclusive of animal models, organoid models and 2D cellular models, possess a distinctive set of advantages and limitations. Kidney organoids offer a middle ground between animal and 2D cell models, with unique advantages being their high throughput potential and expression of a human (potentially patient specific) genome in 3D, and the major drawback being their immaturity and variability. In future a well-considered approach to functional genomic disease modelling will exploit the strengths of each in combination.

2.6.2 Existing literature describing iPSC-derived renal genetic disease models.

At the time this PhD commenced, there were no published examples of iPSC derived kidney organoids used for disease modelling. Since this time the field has made considerable progress and a number of examples have been published.

Prior to the publication of the three landmark protocols for iPSC derived kidney regeneration (Morizane et al., 2015, Takasato et al., 2015, Freedman et al., 2015) the first use of iPSC for functional genomic modelling characterised undifferentiated iPSC derived from 3 patients with ADPKD-*PKDI* and 2 patients with ARPKD as well as patient-iPSC-derived embryoid bodies and hepatoblasts.(Freedman et al., 2013) Pursuing the hypothesis that polycystin 1 is necessary for the ciliary localisation of polycystin 2 (PC2, gene product of *PKD2*), this study found a 75% reduction in the immunofluorescent PC2 expression of *PKDI*^{+/-} heterozygous iPSC cilia (as well as differentiated embryoid bodies and hepatoblasts) when compared to controls.(Freedman et al., 2013) They also demonstrated the capacity to rescue PC2 expression with transfection of wild type *PKDI* vectors in *PKDI* knockout IMCD3 cells.(Freedman et al., 2013) In addition to being one of the first demonstrations of a personalised, patient-specific brand of scientific research, the significance of this study was that reduced ciliary PC2 localisation had only previously been demonstrated in kidney epithelium of established human ADPKD cysts(Nauli et al., 2006, Xu et al., 2007), and thus the same findings described in a range of patient-derived cell types suggested that reduced ciliary PC2 localisation was a product of the constitutional heterozygous *PKDI* variant and not due to an acquired ‘second hit’ or other secondary factor. Without a morphological readout or molecular link to ADPKD, this study could not extend these findings mechanistically to PKD cystogenesis.

In subsequent publications featuring iPSC-derived regenerated kidney tissue, this group would need to engineer a homozygous *PKDI*^{-/-} knockout iPSC line using CRISPR/Cas9 to be able to achieve *in vitro* cystogenesis.(Freedman et al., 2015) Large, epithelial, ballooning cystic structures arose from 6% of *PKDI*^{-/-} organoid tubules, compared to 0% of control cultures.(Freedman et al., 2015) The same authors increased the efficiency of cystogenesis from both *PKDI*^{-/-} and *PKD2*^{-/-} knockout kidney organoids in suspension culture.(Cruz et al., 2017) Cysts were noted to be hyperproliferative by immunofluorescence for phosphohistone H3 compared to controls. Cysts were dissected from the tubular remnant and the two were compared transcriptionally by microarray analysis, suggesting increased MYC and mTOR activity in the cyst.(Cruz et al., 2017) Comparison to control organoids would have been more appropriate. Most recently, in an impressive demonstration of the potential for high throughput screening using their *PKDI*^{-/-} kidney organoid cyst assay, this group screened eight factors thought to modulate

the cell to microenvironment interaction in a 96 well plate.(Czerniecki et al., 2018) The identification of increased cyst swelling during treatment with blebbistatin, a non-muscle myosin II B (NMIIB) inhibitor, has led to the hypothesis of NMIIB activators as potential novel treatment for ADPKD-*PKDI*.(Czerniecki et al., 2018, Helms et al., 2019)

Whilst an impressive body of work, there remain some limitations. For example, the conservation of renal epithelial cell identity in these extended cultures was determined by LTL and ECAD positive immunofluorescence, without any more granular analysis of their transcriptional data or more specific immunofluorescence for markers of renal epithelial identity.(Cruz et al., 2017, Czerniecki et al., 2018) Another limitation is the described inability to translate the protocol to an ADPKD patient-derived iPSC line, as the use of CRISPR engineered *PKDI*^{-/-} and *PKD2*^{-/-} homozygous iPSC do not specifically illustrate the *bona fide* genotype of ADPKD and will not allow for personalised therapeutic screening should this compound eventually reach clinical application.

Whilst not strictly iPSC derived, a comprehensive characterisation of primary kidney and urine derived renal epithelial ‘tubuloids’ was published from Hans Clevers laboratory this year including a number of disease modelling applications.(Schutgens et al., 2019) They demonstrated the infection of in vitro tubules with BK virus and the subsequent treatment of this infection with cidofovir, establishing a model for post-transplant BK virus nephropathy that may be useful for testing novel therapeutics.(Schutgens et al., 2019) Secondly, they modelled Wilm’s tumour by culturing tubuloids established from nephrectomy specimens alongside those established from healthy kidney tissue from the same specimen, demonstrating typical triphasic histology in culture and establishing a tumour-specific, increased expression of *SIX2*, a recognised driver of nephroblastoma. (Schutgens et al., 2019) Finally, they extended their primary intestinal organoid forskolin swelling assay as a model of cystic fibrosis severity to urine derived tubuloids, observing a complex, overfolded morphology of CF patient tubuloids compared to control, and establishing a pathologically diminished swelling response to forskolin treatment (as seen in primary intestinal CF organoids) which improved with pre-treatment of a CFTR potentiator.(Schutgens et al., 2019)

Oculocereborenal Syndrome (eponymously known as Lowe Syndrome) is an X-linked monogenic disorder caused by pathogenic variants in *OCRL* which produces inositol-5-phosphatase.(Recker et al., 2015) In one of the first attempts at patient-iPSC-derived renal disease modelling, Hsieh et al (2018) reprogrammed patient fibroblasts to iPSC and differentiated them to ‘kidney lineage’ cells using 4 days of CHIR99021 followed by 12 days of bFGF and withdrawal of growth factors for a further 9 days. A kidney lineage differentiation end point was characterised by positive immunofluorescence for PAX2, N-cadherin and cadherin-16.(Hsieh et al., 2018) These cells demonstrated reduced rates of ciliogenesis (consistent with previous non-renal cellular modelling in Lowe Syndrome) and retention of SIX2 away from the nucleus in the Golgi apparatus, rescued with lithium treatment.(Hsieh et al., 2018) Additionally, the authors concluded by counting the relative proportions of SIX2+ and CK8+ cells within the monolayer, that OCRL variants patterned mesoderm in favor of ductal structures (CK8+).(Hsieh et al., 2018) This study was limited by the lack of adequate characterisation of the mesodermal cell populations derived, the use of non-isogenic control iPSC lines and use of G-banded karyotyping for quality control of derived iPSC, introducing the possibility that the unexpected phenotypes observed may have been due to unrecognised variants in other genes. The differences in SIX2 and CK8 cellular proportions could well be explained by technical variation in the execution of differentiation or idiosyncratic iPSC line specific factors – a phenomenon now well acknowledged by the field. The conclusions were therefore somewhat speculative without much resolution linking inositol-5-phosphatase to the cellular phenotype identified.

Associate Professor Alan Davidson’s laboratory has published two projects examining inherited kidney disease using their laboratory’s simplified bioreactor protocol for organoid generation.(Przepiorski et al., 2018, Hollywood et al., 2019) The first used CRISPR engineered *HNF1B*^{-/-} knockout iPSC and compared their differentiation to the parental isogenic control iPSC clone in an attempt to model renal cysts and diabetes syndrome (RCAD). They document downregulation of key *HNF1B* transcriptional target genes as well as the failure of the proximal and distal tubular segments to develop within the organoids, consistent with human phenotype and mouse models of the disease.(Przepiorski et al., 2018) A separate report focuses on the lysosomal storage disease cystinosis, and establishes an additive repurposed role for mTOR inhibitor

everolimus to the existing standard of care in cysteamine.(Przepiorski et al., 2018) Organoids from both CRISPR/Cas9 engineered *CTNS* knockout iPSC and patient-derived iPSC demonstrated recognised pathologies of (i) enlarged lysosomes accumulating cystine and cysteine and (ii) reduced cellular basal macroautophagy.(Hollywood et al., 2019) Whilst cysteamine effectively resolved the former, everolimus was demonstrated to rescue the latter.(Hollywood et al., 2019) In undifferentiated iPSC combination therapy appeared to provide additive effect but in iPSC derived organoids, combination therapy appeared no more effective than either alone.(Hollywood et al., 2019)

A number of reports have examined the role of organoids in modelling inherited diseases of the glomerulus.(Hale et al., 2018, Tanigawa et al., 2018, Freedman et al., 2015) In organoids differentiated from *podocalyxin* knockout iPSC, glomeruli demonstrated reduced polarised, linear expression of SYNPO and ZO-1, rather adopting a more diffuse and punctate expression pattern.(Freedman et al., 2015) This finding was restricted to the glomerular segment, consistent with an evolving understanding of podocalyxin as a rare genotype associated with SRNS.(Kang et al., 2017, Barua et al., 2014a) Two reports have examined glomeruli of organoids differentiated from the iPSC of patients with congenital nephrotic syndrome due to biallelic variants in *NPHSI*.(Hale et al., 2018, Tanigawa et al., 2018) Both demonstrated loss of nephrin expression in patient organoid glomeruli by immunofluorescence.(Hale et al., 2018, Tanigawa et al., 2018) Hale et al (2018) used non-isogenic iPSC as a control and also documented reduced expression of podocin and CD2AP (but not kirrel) by immunofluorescence of isolated glomeruli. In a separate report, comparison to a gene corrected control demonstrated restoration of nephrin expression and the widening of gaps (implying restoration of a slit diaphragm) between foot processes on transmission EM.(Tanigawa et al., 2018) Together, these reports establish precedent for the modelling of glomerular disease in kidney organoids.

One of the more significant recent demonstrations of the potential power of the organoid platform in drug discovery came from Associate Professor Anna Greka's laboratory at the Broad Institute.(Dvela-Levitt et al., 2019) ADTKD-*MUC1* is ubiquitously caused by frameshift variants in a variable number of tandem repeats region of the *mucin 1 (MUC1)* gene, and the resultant mutant protein accumulates in the endoplasmic reticulum (ER) in the distal convoluted tubules and activates the unfolded protein response.(Kirby et al.,

2013, Dvela-Levitt et al., 2019) By developing an antibody specific for the frameshift variant gene product (MUC1-fs), this group developed a high throughput screen of a repurposed compound library which was able to detect the preferential clearance of MUC1-fs over the wild type MUC-1 gene product.(Dvela-Levitt et al., 2019) Having narrowed down their library to a single compound of interest, BRD4780, they validated their assay on both genetically engineered mice and kidney organoids differentiated from iPSC of 3 patients with ADTKD-*MUC1*, achieving convincing clearance of the MUC1-fs protein in all cases.(Dvela-Levitt et al., 2019) This novel therapeutic discovery was reported with much greater impact as a result of a demonstrated utility in a regenerated patient-derived human kidney tubule.

2.7 Summary

The human kidney is an anatomically and physiologically complex organ, giving rise to a plethora of distinct inherited disease phenotypes. The functional genomic study of inherited kidney disease using animal and 2D cell culture platforms has increased our theoretical understanding of these diseases. However, these models are limited in their ability to easily translate findings back to human- or patient-specific disease in a clinical context.

A sound understanding of mammalian kidney development, derived largely from the study of mouse models has directly informed the development of protocols for the differentiation of human iPSC derived kidney organoids. Whilst only representative of the immature organ, kidney organoids represent a novel functional genomic platform, capable of complementing the limitations of animal and 2D cell culture models. Most excitingly, iPSC reprogramming from patients with inherited kidney disease offers the opportunity for patient-specific modelling and personalised, *in vitro* therapeutic screening.

A number of kidney organoids have now been published and the field is moving rapidly. A number of groups have modelled adult onset kidney disease, most often using engineered knockout iPSC cells. Our approach has been to model early onset genetic renal diseases using patient reprogrammed iPSC and CRISPR gene edited isogenic control clones. The aims of this thesis are to establish a role for patient-iPSC-derived kidney

organoids in the modelling of both glomerular and tubular disease, initially from known genotypes as proof of concept, and then from novel genotypes. Chapters 3-5 describe three separate projects highlighting the strengths and limitations of iPSC derived kidney organoids as models of inherited kidney disease.

Chapter 3 Patient-iPSC-derived kidney organoids show functional validation of a ciliopathic renal phenotype and reveal underlying pathogenetic mechanisms.

3.1 Preface

At the commencement of this PhD project, kidney organoids were a novel discovery and their potential for disease modelling was hypothesised but yet to be demonstrated. A number of factors were considered in choosing a disease and gene from the patient database for a pilot disease modelling project.

- i. In the primary publication of the protocol, kidney organoids had been transcriptionally profiled and compared to a range of human fetal tissues. They most closely resembled first trimester human fetal kidney, followed by second trimester human fetal kidney.(Takasato et al., 2015) Consequently, the model was felt likely to be more faithful to an infantile phenotype than an adult phenotype, and these pedigrees were prioritised.

- ii. Understanding that kidney organoids lacked urinary drainage, and due to the poorer genetic understanding of CAKUT than more classical monogenic renal diseases, CAKUT was excluded from consideration.
- iii. Disorders of the GBM (eg. Alport Syndrome) were excluded based on the lack of glomerular vasculature and ensuing immaturity of the glomerular basement membrane.
- iv. With the intention of executing a research pipeline that included transcriptional profiling of a purified cell population from the organoids, the method of purification was considered, and Magnetic Activated Cell Sorting of EPCAM+ epithelial cells was considered a straightforward and validated method for this, prompting the prioritisation of tubular epithelial diseases.

Incorporating all of these considerations, a proband presenting with retinopathy at 1 year of age and abruptly with advanced NPHP at 5 years of age secondary to compound heterozygous variants in *IFT140* was selected.

The author-accepted version of the manuscript published in the American Journal of Human Genetics is included below.(Forbes et al., 2018)* Phenotyping of the proband and all clinical information was provided by Peter Trnka, Chirag Patel and Andrew Mallett. Whole exome and genome sequencing and variant curation was performed by Cas Simons and Bruce Bennett. The simultaneous reprogramming and CRISPR gene correction was performed by Sara Howden.

3.3 Abstract

Despite the increasing diagnostic rate of genomic sequencing, the genetic basis of more than 50% of heritable kidney disease remains unresolved. Kidney organoids differentiated from patient-derived induced pluripotent stem cells (iPSC) represent a potential, but unvalidated, patient-specific platform for the functional validation of novel gene variants and investigation of underlying pathogenetic mechanisms. In this study, trio whole exome sequencing of a prospectively identified nephronophthisis (NPHP) proband and her parents identified compound heterozygous mutations in *IFT140*, a gene previously associated with NPHP-related ciliopathies. *IFT140* plays a key role in retrograde intraflagellar transport but the precise downstream cellular mechanisms responsible for disease presentation remains unknown. A one-step reprogramming/gene-editing protocol was used to derive both uncorrected patient and isogenic gene-corrected iPSC which were differentiated to kidney organoids. Patient organoid tubules demonstrated shortened, club shaped primary cilia whilst gene-correction rescued this phenotype. Differential expression analysis of epithelial cells isolated from organoids suggested downregulation of apicobasal polarity, cell-cell junction and dynein motor assembly genes in patient epithelial cells. Matrigel cyst cultures confirmed a defect in polarisation in patient versus gene-corrected renal epithelium. As such, this study represents a ‘proof of concept’ for the use of patient-derived iPSC to model renal disease and illustrates dysfunctional cellular pathways beyond the primary cilium in the setting of *IFT140* mutations, which are established for other NPHP genotypes.(Figure 3.1)

Figure 3.1 Graphical abstract

Summary of experimental approach. First skin fibroblasts obtained from a patient with compound heterozygous variants in *IFT140* were simultaneously reprogrammed to iPSC and gene corrected for one of the pathogenic alleles. Organoids differentiated from these iPSC clones demonstrated clubbed cilia whereas gene corrected cilia demonstrated wild type morphology. Epithelial cyst culture demonstrated impaired lumen formation consistent with RNA profiling from MACS sorted epithelial subfractions.

3.4 Introduction

The kidney is a complex, multicellular organ affected by a wide spectrum of genetic disease, including congenital abnormalities of the kidney and urinary tract, steroid resistant nephrotic syndrome, polycystic kidney disease, tubular electrolyte processing disorders and stone forming nephropathies. Single gene disorders account for up to 10% of adult and 50% of paediatric end-stage kidney disease (ESKD). (Mallett et al., 2014, Fletcher et al., 2013) The ability of next generation sequencing techniques to achieve a genetic diagnosis varies significantly between disease groups. (Otto et al., 2011, Mallett et al., 2017, Halbritter et al., 2013) In addition, the identification of novel gene changes, referred to as variants of unknown significance (VUS) cannot provide a genetic diagnosis without some form of functional evaluation. Modelling of novel VUS has previously been performed in a variety of animal models, including gene knockouts or knockdown in cell lines or model organisms from fly through zebrafish to mouse. However, such animal models are limited by interspecies variation in gene structure and function and an inability to account for the possibility of phenotypic variation arising from patient modifier genes that are not present in the model organism. Patient-derived primary cell lines overcome these limitations, but an *in vitro*, three dimensional, patient-derived renal cellular model is not previously reported.

Recent advances in the directed differentiation of human iPSC towards renal lineages could represent a novel disease modelling platform for functional genomics. (Takasato et al., 2015) The generation of iPSC from patient skin or blood samples is now routine. (Takahashi et al., 2007) Additionally, CRISPR/Cas9-mediated correction of candidate VUS enables the generation of isogenic control iPSC lines, isolating the effect of the VUS within the experimental comparison and removing the confounding influences of genomic variation created by a non-isogenic control. In theory, the comparison of organoids generated from patient and matched gene-corrected iPSC lines should isolate the phenotypic effect of the patient's specific allele. However, kidney organoids currently represent a model of the developing nephron and the demonstration of a disease phenotype within a patient-derived organoid has not previously been demonstrated.

This study explores the utility of kidney organoids as a disease modelling platform in the setting of prospective identification of a paediatric patient with a heritable renal disease. The proband presented with a nephronophthisis related ciliopathy (NPHP-RC) due to compound heterozygous *IFT140* mutations. NPHP is a progressive, fibrocystic renal disease histologically characterised by tubular basement membrane disruption, tubular dilatation and atrophy, interstitial fibrosis and an inevitable decline to ESKD. Whilst rare (estimated prevalence 1 in 50,000-80,000 live births)(Waldherr et al., 1982, Levy and Feingold, 2000), NPHP represents the most common monogenic cause of CKD in the first three decades of life.(Braun and Hildebrandt, 2016) In spite of the discovery of over 40 associated genes, up to 40% of NPHP-RC patients remain undiagnosed following targeted exome sequencing.(Halbritter et al., 2013) Furthermore, the pathogenetic mechanism linking the cilium/centrosome complex to disease phenotype is unresolved. Proposed mechanisms described in the literature vary, including but not limited to disturbances in cell adhesion (Benzing et al., 2001), cell polarity (Donaldson et al., 2002), cytoskeletal function (Bizet et al., 2015, Yasunaga et al., 2015), Wnt signalling (Simons et al., 2005), Hippo signalling (Habbig et al., 2011), centrosomal function (Tammachote et al., 2009) and DNA replication stress (Slaats et al., 2015, Choi et al., 2013a).

A common feature to all genes associated with NPHP-RC is their association with the primary cilium and/or centrosome.(Braun and Hildebrandt, 2016) *IFT140* is a core component of the IFT-A complex which links ciliary maintenance proteins, signalling molecules and transmembrane receptors to the dynein motor complex in order to descend the ciliary axoneme to the basal body, a process known as retrograde intraflagellar transport (IFT).(Stepanek and Pigino, 2016)(Figure 2.4) *IFT140* dysfunction results in a shortened cilium with an accumulation of IFT cargo distending the ciliary tip.(Piperno et al., 1998, Miller et al., 2013)(Figure 3.1) In addition, IFT proteins contribute to the selective importation of targeted proteins into ciliary cytoplasm.(Hirano et al., 2016, Liem et al., 2012, Mukhopadhyay et al., 2010) This includes G-protein coupled receptors important in the negative regulation of hedgehog signalling.(Mukhopadhyay et al., 2013) Beyond these observations, a biological pathway explaining human NPHP disease phenotype is not known.

By demonstrating an established cellular genotype-phenotype correlation within a patient-derived *IFT140* variant kidney organoid, this proof of concept study validates the use of patient-derived kidney organoids for disease modelling and future ratification of novel VUS. Using a simultaneous reprogramming and CRISPR editing protocol (Howden et al., 2015), patient and gene-corrected, isogenic control iPSC were generated from the skin fibroblasts of the patient described above with compound heterozygous *IFT140* mutations. Both iPSC lines were used to generate patient-derived kidney organoids. Within the tubular epithelium of unedited patient organoids, a classical ciliary morphology indicative of retrograde IFT dysfunction was identified. Gene-corrected organoids demonstrated a capacity to resolve this ciliary morphology thereby verifying the genomic variant as disease causing. Additionally, transcriptional profiling and differentiation gene expression analysis using patient-derived and gene-corrected organoids revealed dysfunctional pathogenetic pathways not previously described in *IFT140* mutation but established for other NPHP genes, suggesting this model could clarify the common pathogenetic mechanisms for this heterogenetic rare disease.

3.5 Methods

3.5.1 Genome Sequencing and Analysis

This research was conducted with approval from the human research ethics committees of the Lady Cilento Children's Hospital (HREC/15/QRCH/126), the University of Queensland (MREC Approval 2014000453) and the Royal Brisbane and Women's Hospital (HREC/14/QRBW/34), including research governance approval at all sites. Written informed consent was obtained from the study participant.

Genomic DNA was isolated from peripheral blood using standard techniques. The exome of the proband and each of her parents was captured using the Nextera Rapid Capture Exome kit (Illumina Inc.) then sequenced on an Illumina HiSeq instrument using V4 chemistry (2 × 125nt paired end reads). Read alignment was performed with BWA-mem v0.7.15, variant calling was performed using Real Time Genomics (Hamilton, New Zealand) integrated analysis tool rtgFamily v3.6.2 (Cleary et al., 2014) and annotated using SnpEff v4.1k. (Cingolani et al., 2012) In-house custom analysis pipelines were used to filter and prioritize variants for autosomal recessive or de-novo disease-causal variants

based on the clinical pedigree for the family as previously described.(Vanderver et al., 2016) Segregation of the candidate variants was confirmed using Sanger sequencing.

3.5.2 Derivation and correction of patient iPSC

Gene-corrected and uncorrected iPSC lines were generated from patient dermal fibroblasts using a one-step reprogramming/gene-editing protocol as previously described.(Howden et al., 2015, Howden et al., 2016) Fibroblasts were harvested with TrypLE two days after passaging and resuspended in Buffer R at a final concentration of 1×10^7 cells/mL. 100 μ l of the cell suspension was added to a tube containing reprogramming plasmids (pEP4E02SET2K, pEP4E02SEN2L, pEP4E02SEM2K, pSimple-miR302/367) mRNA encoding SpCas9-Gem, a plasmid encoding a sgRNA that overlaps the patient-specific (c.634G>A) mutation and a repair template plasmid carrying 942 bp (hg38 chr16:1591716-1592658) corresponding to sequence within the *IFT140* gene. The repair template included a 3 bp synonymous change to act as a Cas9-blocking mutation and to facilitate the identification of gene-corrected iPSC clones by allele-specific PCR. Electroporation was performed in a 100 μ l tip using the following conditions: 1400 V, 20 ms, 2 pulses. Following electroporation cells were plated on a 6-well Matrigel-coated plate and maintained in fibroblast media until 4 days post-transfection, and then switched to Essential 7 medium (Essential 8 (E8) medium without TGF β) supplemented with 100 μ M sodium butyrate and changed every other day as described previously (Chen et al., 2011). Sodium butyrate was removed from the media after the appearance of the first iPSC colonies at around day 10. Gene-corrected iPSC were identified by allele-specific PCR and confirmed by Sanger sequencing. One gene-corrected clone and one uncorrected iPSC clone were selected and expanded for further analysis. Karyotype was confirmed by Infinium CoreExome-24 DNA microarray (Illumina) and cells tested negative for mycoplasma contamination. Pluripotency of iPSC lines was confirmed by flow cytometry after staining with antibodies to pluripotency markers (EPCAM, CD9, SSEA4).

3.5.3 Cell Culture and Directed Differentiation to Kidney Organoids

Undifferentiated iPSC were maintained in feeder free conditions on hESC qualified Matrigel in E8 media. One day prior to differentiation, iPSC were dissociated from 60-70% confluence with TrypLE (Thermo Fisher) and plated at 3.5×10^4 cells per cm^2 in a

6 well plate on hESC qualified Matrigel (BD Biosciences) in 2.5mL E8 media supplemented with Revitacell (Thermo Fisher). The following morning, cells were treated with 8 μ M CHIR99021 in APEL2 basal media (STEMCELL Technologies) supplemented with 3.5% Protein Free Hybridoma Media 2 (PFHM2) and Antibiotic-Antimycotic (Life Technologies) for 4 days, followed by FGF9 (200ng/mL) and heparin (1 μ g/mL) for 3 days, changing media every two days. At day 7, cells were dissociated with trypsin 0.05% and 0.25 x 10⁶ cells were spun 3 times at 300g in 1.5mL tubes. Using a large bore P200 pipette tip, pellets were transferred to a Transwell 0.4 μ m pore polyester membrane (CLS3450 Corning). Pellets were cultured over APEL2 + 3.5% PFHM2 + Antibiotic-Antimycotic supplemented with 5 μ M CHIR 99021 for 1 hour followed by FGF9 (200ng/mL) and heparin (1 μ g/mL) for 5 days. Transwell culture continued without added growth factors for up to 24 days changing media three times a week.

3.5.4 Immunofluorescence

Organoids were fixed at the desired time-point with 2% paraformaldehyde for 20 mins on ice and washed three times with PBS. Organoids were incubated with 10% donkey serum, 0.3% Triton X/PBS overnight at 4°C. Primary antibodies were incubated for 48 hours in the blocking buffer at 4°C. Following 6 washes with 0.3% Triton X/PBS, secondary antibodies were incubated overnight at 4°C. Where applicable, DAPI staining was applied at 1:1000 for 3 hours. Following 4 washes with PBS, organoids underwent immunofluorescent imaging with a Zeiss LSM 780 confocal microscope. For ciliary length analysis, three images were captured from two separate experiments. 100 cilia per image were measured in ZEN (v2.3, Zeiss) and statistical analyses performed in GraphPad Prism using unpaired t test with Welch's correction for unequal variance.

Spheroid culture assays were fixed and stained according to a previously published protocol.(Giles et al., 2014) Matrigel was dissolved and spheroids fixed with 4% paraformaldehyde at room temperature for 30mins. Spheroids were washed with DPBS with 1mM CaCl₂ and 1mM MgCl₂ and blocked with a gelatine based permeabilisation buffer (DPBS, 1mM CaCl₂, 1mM MgCl₂, 7mg/mL gelatine and 0.5% Triton X) for 1 hour before overnight incubation with primary antibodies in permeabilization buffer at 4°C. Spheroids were washed four times with permeabilization buffer and incubated with secondary antibodies overnight. Following incubation with FITC-conjugated phalloidin

for 1 hour and DAPI for 10 minutes, spheroids were washed with DPBS with CaCl₂ and MgCl₂ three times and mounted with Prolong Diamond Antifade Mountant.

Primary antibodies used included: anti-NPHS1 (Bioscientific, AF4263, 1:300), biotinylated Lotus tetragonolobus lectin (LTL) (Vector Laboratories, B-1325, 1:300), anti-CDH1 (BD Biosciences, 610181, 1:300), anti-CDH1 (Cell Signalling Technologies, 3195S, 1:300), anti-GATA3 (R&D Systems, AF2605, 1:300), anti-acetylated tubulin (Sigma Aldrich, T6793, 1:500), anti-IFT140 (Proteintech, 17460-1-AP, 1:100), anti-WDR19 (Proteintech, 13647-1-AP, 1:100), anti-IFT88 (Proteintech, 13967-1-AP, 1:100), anti-EpCAM-AF488 (Biolegend, 324210, 1:300), anti-ZO1 (Life Technologies, 40-2300, 1:200), anti-beta catenin (Sigma Aldrich, C2206, 1:200), Phalloidin-FITC (Sigma-Aldrich, P5282, 1:1000).

Secondary antibodies included: Streptavidin Alexa Fluor 405 conjugate (Life Technologies, S32351, 1:400), Alexa Fluor 488 Donkey anti-mouse IgG (H+L) (Invitrogen, A21202, 1:400), Alexa Fluor 568 Donkey anti-rabbit (H+L) (Invitrogen, A10042, 1:400), Alexa Fluor 647 Donkey anti-sheep (H+L) (Invitrogen, A21448, 1:400), Alexa Fluor 647 Donkey anti-goat IgG (H+L) (Invitrogen, A21447, 1:400), Alexa Fluor 647 Donkey anti-mouse IgG (H+L) (Invitrogen, A31571, 1:400), Alexa Fluor 568 Donkey anti-mouse IgG (H+L) (Invitrogen, A10037, 1:400).

3.5.5 *Ciliary Morphology Assessment*

Raw confocal images of cilia were median filtered (radius = 2) and segmented using a Fiji script (Schindelin et al., 2012) to implement the watershed, region labelling, and volume filtering (minimum = 200 voxels) functions from the MorpholibJ library. (Legland et al., 2016) Labelled images were processed using a custom Python script to isolate and maximum project labelled regions representing a single cilium and then randomly select a subset of cilia from the combined dataset for scoring. The program generates blinded and unblinded scoring tables referencing a randomised, multi-image tiff file of individual cilia sampled from both genotypes. Image sets were spiked with automatically generated images (solid greyscale circles) to allow the scorer to reference their position within a 1000 image set whilst scoring. Tiff files were manually scored and referenced back to

their genotype using the unblinded table. Proportions were compared using chi-squared contingency tests in GraphPad Prism.

3.5.6 RNA Sequencing

RNA from the epithelial fraction of whole kidney organoids was extracted using Invitrogen PureLink Mini RNA (Invitrogen) extraction kit including treatment with PureLink DNase Set (Invitrogen), and sequencing libraries prepared using Illumina's TruSeq stranded total RNA protocol with RiboZero rRNA depletion. In total, six samples (three from each iPSC clone) were sequenced using an Illumina NextSeq 500 sequencer at the Translational Genomics Unit, Murdoch Children's Research Institute, Australia. The data was submitted to GEO (GEO accession number: GSE107230). The raw reads were quality and adapter trimmed using trimmomatic v0.35 (Bolger et al., 2014) and mapped to the human genome (hg38) using STAR v2.5.2a (Dobin et al., 2013) in the two-pass mapping mode. Reads were summarised over genes using featureCounts (Liao et al., 2014) and GENCODE V20 annotation. Genes that had expression levels of at least one count per million in at least three samples were kept for further analysis. The data was TMM normalised (Robinson and Oshlack, 2010) and voom transformed (Law et al., 2014). Differential gene expression (DGE) was initially identified with robust paired moderated t-tests in the limma R Bioconductor package (Ritchie et al., 2015) applying a false discovery rate cut-off of less than 5%. This identified 1097 down-regulated and 1244 up-regulated genes in the corrected iPSC versus uncorrected iPSC lines. Testing for enrichment of the Broad Institute's Hallmark gene sets (see Web Resources) was performed using CAMERA (Wu and Smyth, 2012). To further refine the list of differentially expressed genes, we removed 570 genes from the DGE analysis that we have previously identified as being highly variable experiment to experiment and are therefore likely to be false positives (Table 3.3), and restricted our focus to significant significantly up- and down-regulated DGE (adjusted $p < 0.01$, $n = 954$). Gene set enrichment analysis of these 308 genes was performed using the ToppGene Suite (Chen et al., 2009). Downregulated DGE analysis (log fold change < -0.7 , $n = 308$) was performed utilising an adjusted p -value cut off of < 0.05 . Histograms and heatmaps were generated using GraphPad Prism (v7.01). Protein Interactomes were generated using STRING v10.5 (Szklarczyk et al., 2015) and nodes were recoloured from GraphPad Prism heatmaps in Adobe Illustrator (Adobe, v2015.2.1).

cDNA was generated from RNA samples using GoScript™ Reverse Transcription Kit (Promega) and qPCR validation of selected differentially expressed genes was performed using SensiFAST SYBR Lo-ROX Kit (BIOLINE) and QuantStudio5 Real-Time PCR System (Thermo-Fisher).

3.5.7 *Magnetic Associated Cell Sorting (MACS) and Cyst Culture*

Twelve whole organoids were dissociated in 2.0mL TrypLE Select (Thermo Fisher) for 12 minutes and inactivated by dilution with chilled MACS buffer solution (PBS, 2mM EDTA and 0.5% bovine serum albumin). The cell solution was passed sequentially through a 70µm, 40µm and 30µm sieve. Cells were counted, centrifuged at 300g for 5 minutes and resuspended in 300µL of MACS buffer and 100µL of EpCAM+(CD326) Microbeads (Miltenyi Biotech) for 30 minutes. Cells were rinsed with MACS buffer and centrifuged twice before resuspending in 500µL of MACS buffer and passage through an MS MACS column according to the manufacturer's protocol (Miltenyi Biotech). The EpCAM+ fraction was eluted gently from the column in chilled Renal Epithelial Cell Growth Medium 2 (RECGM2, Promocell). 1.0×10^6 cells in 100µL of RECGM2 was mixed with 100µL Matrigel GFR (BD Biosciences) and plated immediately into an 8 well chamberslide. Cell/Matrigel suspension was incubated at 37 °C for 30 minutes before the addition of 200 µL RECGM2 supplemented with 1x Revitacell overnight. RECGM2 without Revitacell was refreshed daily until spheroids were visible by bright field microscopy. Following fixation and immunofluorescent staining (as above) spheroids were imaged with a Zeiss LSM 780 confocal microscope. One hundred consecutive spheroids were assessed per condition and proportions were compared statistically in GraphPad Prism (version 7.01) using Fisher's exact test. Cilia per nucleus was manually counted in 10 epithelial cysts imaged at higher resolution in Fiji using Cell Counter plugin. Mean cilia per nucleus expressed as a percentage for each clone were compared with GraphPad Prism (v7.01) using unpaired t test with Welch's correction for unequal variance.

3.5.8 *Simple Western Blot*

1.0×10^6 EPCAM+ cells were centrifuged in cold MACS buffer and then lysed in RIPA buffer with protease inhibitor (1:500) for 15 minutes on ice. Lysates were vortexed for 45 seconds and centrifuged at 13.3g for 10 minutes at 4°C. The supernatant was collected

and diluted 1:5 with 1x Sample Buffer (ProteinSimple). Protein quantification was performed using a 66-440kDa plate in a ProteinSimple Wes Capillary Western Blot analyser according to the manufacturer's instructions.

3.6 Results

3.6.1 Identification of compound heterozygous *IFT140* mutations reclassifies patient phenotype to Mainzer-Saldino Syndrome

The patient was diagnosed with retinitis pigmentosa (RP) at 1 year of age (Figure 3.2A) and ESKD at 6 years of age, suggesting a phenotype of Senior Løken Syndrome (SLS [OMIM: 266900]). SLS is a NPHP-RC syndrome describing the co-occurrence of retinal and renal ciliopathy. Renal ultrasound identified two kidneys of appropriate size for age displaying increased renal cortical echogenicity and loss of corticomedullary differentiation without any visible cysts. (Figure 3.2B) Renal biopsy was not performed as it was felt unlikely to contribute any diagnostic features beyond those of advanced, end-stage kidney fibrosis. Neither her non-consanguineous parents nor any of her three siblings showed signs of disease and there was no extended family history of renal or other inherited disease (Figure 3.2C).

Trio exome sequencing analysis identified compound heterozygous, single base pair mutations in *IFT140* confirmed by Sanger sequencing to exist *in trans* (NM_014714.3:c.634G>A; p.Gly212Arg; NM_014714.3:c.2176C>G; p.Pro726Ala) (Figure 3.2D). Both sites are highly conserved throughout the vertebrate lineage (Figure 3.2E), and are predicted to be damaging by Polyphen, MutationTaster and CADD. Both mutations have low population allelic frequencies of 4.1×10^{-6} and 5.4×10^{-5} respectively (Table 3.1). The c.634G>A mutation is located at the -1 position of the splice donor site of exon 6. This mutation has been previously described in patients with Mainzer-Saldino Syndrome (MSS) and Jeune's Asphyxiating Thoracic Dystrophy (JATD) (both SRTD9 [OMIM: 266290]) and validated by expression of FLAG-tagged transcripts in immortalised human retinal pigmented epithelial (RPE) cells, suggesting mislocalisation of the protein away from the primary cilium. (Perrault et al., 2012) The nucleotide c.G634 is totally conserved in all vertebrates and the c.634G>A mutation is predicted to disrupt the activity of the donor splice site. (Desmet et al., 2009) The c.2176C>G mutation has not previously been described.

Figure 3.2 Whole exome sequencing (WES) leads to revision of clinical phenotype (A) Patient retinal photograph demonstrate retinitis pigmentosa and (B) Renal ultrasound demonstrating echogenic kidney with loss of corticomedullary differentiation form the basis of the eponymous diagnosis of Senior Loken Syndrome prior to WES. (C) Trio WES identifies compound heterozygous *IFT140* mutations (* indicates sequenced individual.) (D) *IFT140* protein structure with mutation loci identified. (E) Conservation of both amino acid loci across vertebrate species. (F) Following identification of *IFT140* mutations skeletal survey found cone-shaped epiphyses in the phalanges of the hand and foot (white boxes), flattened femoral heads (black arrowhead) and widened femoral neck (white arrowheads) consistent with Mainzer-Saldino Syndrome.

^b Human Splicing Finder web service, <http://www.umd.be/HSF3/index.html> (Desmet et al., 2009)

^c PS, pathogenic strong; PM, pathogenic moderate; PP, pathogenic supporting (Richards et al., 2015)

Compound heterozygous mutations in *IFT140* have not previously been associated with SLS but are reported as a cause of JATD and MSS which are distinguished by classical skeletal phenotypes. (Perrault et al., 2012, Schmidts et al., 2013, Beals and Weleber, 2007) A subsequent skeletal survey in the patient identified flattened femoral heads with widened necks as well as cone shaped phalangeal epiphyses (Figure 3.2F), revising her phenotype to MSS.

3.6.2 *Simultaneous reprogramming and gene-correction of patient fibroblasts*

Using a previously described one-step protocol that combines both an episomal-based, reprogramming strategy and CRISPR/Cas9-mediated gene-editing (Howden et al., 2015), clonal uncorrected and gene-corrected iPSC lines were generated within a single experiment (Figure 3.3A). The Cas9 repair template included correction of the c.634G>A mutation as well as an additional synonymous three base pair change to facilitate identification of corrected clones and prevent Cas9-mediated cleavage following successful homology directed repair (Figure 3.3A). Gene-correction was identified in 1 of 44 screened iPSC clones (2.3%). One uncorrected patient (henceforth referred to as 'PT') and the isogenic, gene corrected clone ('GC') were carried forward to further experiments. Pluripotency was confirmed by culture morphology and staining for common pluripotency markers and subsequent flow cytometry. (Figure 3.4A,B)

3.6.3 *Gene-correction of iPSC rescues unstable mRNA transcript*

The patient-specific mutations were confirmed following Sanger sequencing of PCR amplicons spanning exon 6 or exon 18 of the *IFT140* locus (Figure 3.3C, red arrowhead) whereas loss of the c.634G>A mutation and gain of the synonymous three base pair change was confirmed in gene-corrected iPSCs.

Total RNA was extracted and RT-PCR was performed to amplify *IFT140* transcripts from gene-corrected and uncorrected patient iPSCs, which were then sequenced. This analysis revealed that only the c.2176C>G allele was detectable at the transcriptional level in uncorrected iPSCs (Figure 3.3C). This indicates that the c.634G>A mutation results in defective splicing of exon 6 and the incorrectly spliced transcripts are potentially targeted for degradation. Hence only one allele of the *IFT140* gene is likely to be transcribed and translated. In contrast, transcription from both alleles was detected in gene-corrected

Figure 3.3 Gene-correction, transcript analysis and differentiation to kidney organoid (A) The gene-correction template for the c.634G>A mutation contains the corrected single base pair (blue) and a synonymous downstream three base pair substitution (green) for ease of identification by Sanger sequencing. Successfully reprogrammed clones are screened for unsuccessful (red nuclei, PT) or successful (green nuclei, GC) gene-correction. (B) DNA sequencing demonstrates the c.634G>A mutation in the PT clone (red arrowhead) and successful correction of this mutation in the GC clone (green arrowhead) as well as the synonymous 3 base pair change in this allele (grey shading). (C) Sanger sequenced RNA (copy DNA) transcripts suggests the mutant allele is not detectable as a stable transcript indicated by a single chromatogram peak at both the c.634G>A locus (red arrowhead) and the c. 2176C>G mutation (blue arrowhead) in the PT clone. The double chromatogram peak at the synonymous 3 base pair substitution (grey) and the c. 2176C>G mutation locus (not gene-corrected; blue) in the GC clone indicates gene-correction has rescued this transcript. (D) qPCR identifies 50% relative mRNA expression in the PT iPSC compared to control. (data represented as mean + 95% confidence interval, $p=0.0001$) (E) Capillary western blot reveals 43% relative IFT140 protein expression in PT differentiated renal epithelial cells compared to GC. (data represented as mean + 95% confidence interval, $p<0.001$) (F) Bright field images of kidney organoids on day 25 of culture (day 18 of aggregate culture, scale bar 1mm). (G) Immunofluorescence images of whole organoids demonstrate balanced expression of glomerular precursors (NPHS1; white), proximal tubule, (LTL; blue), distal tubule (CDH1, green) and collecting duct (CDH1/GATA3, green/red). Scale bar 1mm in low magnification and 50um in high magnification images.

Figure 3.4 Pluripotency of iPSC clones and differentiation to kidney organoids
 (A) Pluripotency analysis of PT and GC iPSC clones. (B) Bright field images of PT and GC iPSC clones demonstrating iPSC morphology: tightly packed colonies with shiny edges. Scale bar 200um. (C) Differentiation protocol adapted from Takasato et al.(Takasato et al., 2016) See methods section for details. (D) Bright field images of differentiation demonstrate epithelial to mesenchymal transition between day zero and day four. Cultures become raised and rugated by day seven and self-organised structures are evident by day twelve, which mature with further culture. Monolayer scale bar 200um. Aggregate scale bar 500um.

iPSCs as evidenced by presence of the synonymous 3 base pair change adjacent to the corrected mutation.(Figure 3.3C) This was also supported by the finding of 53% *IFT140* mRNA and 33% protein expression in the PT clone relative to the GC clone (Figure 3.3D,E).

3.6.4 *Kidney organoid tubules demonstrate ciliary morphology consistent with defective retrograde IFT*

Multicellular kidney organoids were differentiated from both patient and control iPSC lines (Figure 3.3F) adapting a protocol previously published by Takasato et al (2015) to one which used fully defined, serum and feeder free culture conditions.(Figure 3.4C) Organoids produced from both lines were validated as reaching a renal end-point by the contiguous immunofluorescent expression of nephrin (NPHS1, staining glomerular precursors), *Lotus tetragonolobus* lectin (LTL, staining proximal tubule), cadherin 1 (CDH1, also known as ECAD, staining distal tubule) and co-immunofluorescence for CDH1 and GATA3 (collecting duct) (Figure 3.3G).

Previous *IFT140* null mouse models demonstrated shortened primary cilia with swollen ciliary tips in developing limb buds.(Miller et al., 2013) It should be noted that dual *IFT140* knockout resulted in embryonic lethality.(Miller et al., 2013) Acetylated tubulin and ARL13B stained primary cilia were clearly identified in the tubular epithelium of iPSC-derived kidney organoids by immunofluorescence (Figure 3.5A,D). Automated image processing was used to generate a random series of images of individual cilia from CDH1+ regions of kidney organoids ($n = 900$ cilia) for blinded scoring (Figure 3.5A). A clubbed morphology similar to that seen in the murine *IFT140* null was evident in the majority of PT cilia (59%; 95%CI 54-63%) whilst a similar majority of GC cilia (60%; 95%CI 56-65%) demonstrated wild type morphology (Figure 3.5B). PT cilia were significantly shorter than GC cilia and the difference between PT and GC mean ciliary length increased with time in aggregate culture (Figure 3.5C). Ciliary *IFT140* expression within club shaped cilia in GATA3+ regions of organoid tubules demonstrated increased *IFT140* staining of the swollen ciliary axoneme. Other IFT-A and B proteins demonstrated a similar intensification of fluorescence in the ciliary tip consistent with defective retrograde IFT. (Figure 3.5D)

Figure 3.5 Patient organoid tubules demonstrate abnormal cilia which are rescued by gene-correction (A) Cilia of CDH1+ tubular epithelial cells demonstrate classical morphology associated with defective retrograde IFT: short with swollen ciliary tips (left and middle panels, scale bar $2\mu\text{m}$). Individual cilia were isolated from these images (right panels, scale bar 500nm) and shuffled for blinded scoring of morphology. (B) Quantitative output of blinded cilia morphology analysis demonstrating predominantly clubbed cilia in PT organoids (59%) and predominant wild-type morphology in gene corrected cilia (61%) ($n = 900$, $p < 0.0001$, Chi-squared test). (C) PT cilia were shorter than GC cilia at every culture time point, with an increasing difference noted with time in culture ($n = 600$ cilia per condition, $p < 0.0001$, Welch's t test, error bars represent mean + 95% confidence interval). (D) IFT components IFT140, WDR19 and IFT88 were all found to accumulate in the PT ciliary tip. Gene corrected organoids displayed wild type distribution (scale bar $1\mu\text{m}$).

3.6.5 *Transcriptional profiling identifies dysfunctional cellular processes resulting from c.634G>A mutation*

The isolated transcriptional effects of the c.634G>A mutation were investigated by comparing bulk RNA sequencing profiles (GEO accession number: GSE107230) of the epithelial (EPCAM+) cell fractions isolated from iPSC-derived kidney organoids by magnetic activated cell sorting (MACS) (Figure 3.7A). Based on co-immunofluorescence analysis, this EPCAM+ fraction included proximal tubule (LTL+) and collecting duct structures (GATA3+) as well as an epithelial structure resembling Bowman's capsule surrounding visceral epithelial cells (Figure 3.6A,B). Validation of EPCAM+ purification by MACS was confirmed by flow cytometry (Figure 3.6C). Replicates clustered appropriately on a principle component analysis with clear separation between PT and GC transcription profiles upon unbiased clustering. (Figure 3.7B,C).

For the purposes of gene enrichment analysis, the primary differential gene expression (DGE) dataset (Table 3.2) was filtered for genes that have previously exhibited high transcriptional variability between repeated differentiation experiments of a human wild-type iPSC cell line (CRL1502, clone C32).(Phipson et al., 2017) This transcriptional 'noise' is batch associated and likely to result from slight variations in relative maturation between individual organoids. Any of the top 1000 most variable genes within the CRL1502 dataset were excluded from further analysis ($n = 570$, Table 3.3).

Gene enrichment analysis of remaining genes with significant DGE (adjusted p value <0.01 , $n=954$; Table 3.4) returned gene ontology (GO) terms illustrating disturbances in cell adhesion and cytoskeletal interaction pathways (Figure 3.7D). This analysis returned one single human phenotype term 'Vitreoretinal Degeneration' (HP:0000655), consistent with the patient phenotype (Figure 3.8A) and inclusive of *CRBI*, a critical component of the highly conserved Crumbs polarity complex which is strongly associated with RP and Leber's Congenital Amaurosis.(den Hollander et al., 2001) Cell polarity complexes are highly conserved, critical regulators of epithelial polarity modulating asymmetrical cytoskeletal organisation within the cell, and cell junction integrity in order to preserve apicobasal expression of transmembrane receptors and transporters.(Pieczynski and Margolis, 2011) Differential expression of Crumbs complex genes within the primary

Figure 3.6 Characterisation and validation of EPCAM MACS sorting.

 (A) Diagrammatic representation of epithelial magnetic associated cell sorting (MACS) from dissociated organoids. Dissociated organoids were incubated with EPCAM antibody conjugated magnetic beads and passed through a magnetic field, trapping epithelial cells which could be gently eluted for downstream application following removal of the magnetic field. (B) Principal component analysis of primary RNA sequencing data demonstrates clustering of PT and GC replicates. (C) Heatmap demonstrates consistency of gene expression across replicates. (D) Top GO terms output from ToppGene gene list enrichment of *Set 1* (combined up and downregulated genes with significant differential expression adjusted $p < 0.01$; top graph) and *Set 2* (genes with log fold change > 0.7 favouring GC and significant differential expression < 0.05 ; bottom graph). Bar represents $-\log_{10}(p \text{ value})$ and adjacent fraction represents number of genes within the data set (numerator) and number of genes within the GO gene list (denominator). Similar GO terms with near-identical DGE representation and GO term have been filtered out to avoid repetition. Blue: GO Molecular Function, Purple: GO Biological Process, Orange: GO Cellular Component.

RNASeq dataset suggested downregulation in PT renal epithelia compared to GC (Figure 3.8B). Transcriptional differences within the associated PAR polarity complex were less consistent between replicates with the exception of *CDC42* which was downregulated in PT (Figure 3.8C). Of interest, animal knockout models of *Cdc42*^{-/-} develop a NPHP-like renal histology and demonstrate loss of photoreceptor cilia.(Choi et al., 2013b) *CDC42* was also a central node within a STRING protein interaction network of DGE highlighted within the ‘Adherens Junction’ term (GO:0005912, Figure 3.9A,B). *EGFR* was also a downregulated central interacting gene product identified by STRING protein interactome with significant downregulated expression. *EGF* signalling is strongly associated with the proliferative epithelial phenotype seen in ADPKD cysts and inhibition of this signalling pathway reduces cyst progression in animal models (reviewed in (Harskamp et al., 2016)). The observation of *CDK1* (int:CDK1) and *CDK2* (int:CKD2) in the top 5 interacting gene products is of interest given increasing evidence of benefit in both animal and cellular nephronophthisis models when treated with CDK-inhibitors.(Booij et al., 2017, Srivastava et al., 2017b, Bukanov et al., 2012, Moreno et al., 2008)

IFT related ciliopathy is often associated with increases in canonical Wnt, Shh and Notch signalling pathways, usually amplified by treatment with a pathway agonist.(Liem et al., 2012, Hynes et al., 2014, Mukhopadhyay et al., 2013) Whilst these pathways did not feature prominently in ToppGene enrichment analysis, all three signalling pathways were upregulated in Hallmark gene list enrichment analyses on the primary dataset before the exclusion of highly variable genes (Figure 3.9D-F). In a murine *IFT140 HoxB7-Cre* knockout model, transcriptional changes in these signalling pathways were not observed until post-natal day 15-20.(Jonassen et al., 2012) The present study, however, demonstrates changes in these pathways consistent with the existing literature, within a model that transcriptionally most closely resembles first trimester human foetal kidney.(Takasato et al., 2015)

Gene enrichment analysis of downregulated DGE reflected disturbances to apical and basolateral plasma membranes, the apical junction complex as well as downregulated transporter activities associated with these cellular membranes (Figure 3.7D). Additional

downregulated GO outputs of interest included ‘negative regulation of epithelial cell proliferation’ (GO:0050680) and ‘axonemal dynein complex assembly’ (GO:0070286; Figure 3.9C,D). RNA sequencing of selected differentially expressed genes from these GO terms was validated by qPCR (Figure 3.12).

3.6.6 Impaired spheroid culture in *IFT140*(-/-) epithelial cells sorted from kidney organoids

The differential expression profiling highlighted downregulation of genes expressed in the apical part of the cell and the cell junction (Figure 3.10A,B). The functional validation of apicobasal polarity defects using three dimensional epithelial spheroid culture has previously been applied in the study of ciliopathies.(Giles et al., 2014) Accordingly, MACS sorted EPCAM+ cells from both PT and GC organoids were subjected to spheroid culture and stained with markers of apical junctions (ZO-1 and CDH1) and apicobasal polarity (acetylated tubulin and beta-catenin) (Figure 3.10C). Consistently fewer PT EPCAM+ cells developed spheroids with polarised epithelium when compared with GC EPCAM+ cells (PT 34.0% [25.4-43.7], GC 53.0% [43.2-62.5]; $p = 0.01$; Figure 3.10D). This confirms the utility of spheroid culture as an assay for evaluation of cellular polarisation using patient-derived renal epithelium and indicates an underlying defect in cell-cell interactions potentially present during human development. Assessment of primary cilia per nucleus was technically challenging in whole 3D organoids but manual counting in cultured cysts was more straightforward. Cilia per nucleus was reduced in PT cysts compared to GC cysts and also demonstrated increased variability (Figure 3.11) (PT 83.7% [74.7-89.3], GC 93.8% [91.1-96.7]; $p < 0.01$).

3.7 Discussion

This study presents the prospective application of patient-originated iPSC derived kidney organoids for functional genomic disease modelling. We demonstrate the utility of an isogenic, gene-corrected control iPSC clone for the functional validation of an isolated, patient-specific gene mutation. The demonstration of such a clear restoration of renal ciliary morphology by gene-correction of a single mutated allele of an autosomal recessive genotype supports the likely efficacy of this approach for validation of novel VUS in future studies. Previous reports of iPSC-based renal disease modelling have relied on the generation of mutations using CRISPR/Cas9-induced non-homologous end joining

Figure 3.9 Differential expression within adherens junction and axonemal dynein assembly GO terms with STRING protein interactomes
 (A) Heatmap demonstrating differential expression of genes from Adherens Junction GO Term (adjusted $p < 0.01$ for all genes). (B) STRING protein interactome of Adherens Junction DGE. Node colours represent average differential expression in of the PT triplicate relative to average of GC triplicate. Thickness of lines indicates strength of data supporting the shared function between the proteins. Protein nodes without interactions have been hidden. (C) Heatmap demonstrating differential expression of genes from Dynein Complex Assembly GO Term (* indicates adjusted $p < 0.05$, ** indicates adjusted $p < 0.01$). (D) STRING protein interactome of Dynein Complex Assembly DGE. Node colours represent average differential expression in of the PT triplicate relative to average of GC triplicate. Thickness of lines indicates strength of data supporting the shared function between the proteins. No omitted nodes.

Figure 3.10 Spheroid culture demonstrates functional assay of disturbed apicobasal polarity in patient organoid epithelium (A,B) Heatmaps demonstrating significant downregulation of components of apical part of the cell and apical cell junction in patient line (red indicates expression above the mean, blue indicates expression below the mean, * signifies $adj\ p < 0.01$). (C) Immunofluorescent images from spheroid culture of EPCAM+ MACS sorted epithelial cells demonstrating examples of poorly polarised structures (PT), well polarised structures (GC) and reference images from IMCD3 cells. (D) PT EPCAM+ cells were less able to establish polarised spheroids than GC controls. (PT 34.0% [25.4-43.7], GC 53.0% [43.2-62.5]; $p = 0.01$; error bars represent 95% confidence interval).

Figure 3.11 Cilia per nucleus measured from epithelial cyst culture
 Mean cilia per nucleus counts from cyst culture demonstrate small but significant reduction in ciliation in PT cysts compared to GC cysts (PT 83.7% [74.7-89.3], GC 93.8% [91.1-96.7]; $p < 0.01$; error bars represent 95% confidence interval).

in wildtype human cell lines.(Cruz et al., 2017, Freedman et al., 2015) Patient-iPSC-derived kidney organoids model not only the patient-specific alleles for any candidate variant, but also the genomic background of that patient, allowing for contributions to phenotype from gene modifiers or allowing multigene disorders to be dissected. Importantly, if a modelled candidate VUS proves ultimately non-disease associated, data derived from the study of the patient-derived organoids continues to express the *bona fide* VUS potentially permitting a retrospective diagnosis.

Whilst the functional genomic study of human ciliopathy has previously relied on animal models, immortalised cell-based models or patient-derived fibroblast monolayers, an increasing body of evidence advocates that differences in ciliary biology occur between species(Lu et al., 1999, Wu et al., 2002, Karlstrom et al., 2003, Park et al., 2000, Shimeld et al., 2007, Briscoe and Therond, 2013) and between cell types in the same individual.(Shimada et al., 2017) This emphasises that modelling a human renal disease in a human renal tissue model is essential for the future application to human patients in a clinical setting. Additionally, generation of transgenic models of allelic insufficiency by knockdown with morpholino oligomers, silencing mRNA or gene knockout fails to recapitulate the specific allelic dysfunction for the individual patient. This is especially pertinent for a gene such as *IFT140*, which is frequently characterised by a compound

heterozygous genotype creating a spectrum of gene dysfunction and variable phenotypes as a result of different allelic permutations.(Perrault et al., 2012, Schmidts et al., 2013) Indeed, the c.634G>A allele present in this patient has been previously studied by expression of a FLAG-tagged variant transcript in immortalised RPE cells, suggesting mislocalisation of this variant IFT140 protein.(Perrault et al., 2012) Our results, however, suggest lack of a stable transcript from the c.634G>A allele resulting in a 50% reduction in mRNA and protein consistent with probable mRNA transcript decay. The ability to examine the specific transcriptional consequence of a single base pair mutation against an isogenic control is a novel and unique advantage of this disease modelling approach.

Transcriptional profiling of epithelial cells sorted from patient-derived organoids and gene corrected controls yielded results consistent with the evolving literature on *IFT140* dysfunction. Integral components of dynein motor assembly were found to be downregulated in PT organoid epithelium. This observation supports a growing body of evidence for a novel role of IFT140 (and other IFT-A proteins) in maintaining retrograde IFT activity by ciliary import and assembly of dynein motor components, rather than solely for the linking of ciliary proteins to the dynein motor for axonemal descent.(Blisnick et al., 2014)

The apparent success of our approach is likely critically associated with the use of patient and isogenic corrected lines to reduce genetic variation between test and control. However, acknowledging the variability in gene expression within a regenerative disease modelling platform is essential for the accurate interpretation of disease-associated transcriptional change. Here we apply a novel approach that is based upon an extensive prior evaluation of the source of transcriptional variability between kidney organoids.(Phipson et al., 2017) It is possible that a portion of those genes removed from the analysis did represent genes of relevance to the disease state rather than simple experimental variation. To investigate this further, an isolated gene enrichment analysis of the excluded 570 genes returned GO terms associated with plasma membrane transporter activity and kidney/urogenital system development. Such terms are related to relative maturation of nephrons within organoids, which we have shown does vary, but could also be attributed to the *IFT140* mutations. Importantly, where a gene was

associated with the disease state in our analyses, we have investigated gene changes in all genes for linked GO terms in order to more comprehensively evaluate pathway changes.

Over 40 genes have been identified as related to NPHP and all are linked with the primary cilium/centrosome complex.(Braun and Hildebrandt, 2016) Within this group, a variety of proposed disease mechanisms exist for NPHP gene products but no unifying pathogenetic mechanism is known. Cell junction, apicobasal polarity and cytoskeleton terms featured strongly in our DGE analysis. Whilst these pathways have not previously been described in IFT140 dysfunction, they have been implicated in NPHP pathobiology since the discovery of the first NPHP genes.(Donaldson et al., 2002, Otto et al., 2003, Delous et al., 2009, Yasunaga et al., 2015) A cytoplasmic role for IFT-B protein IFT54 (*NPHP20*) in the negative regulation of microtubule stabilisation by its interaction with MAP4 has recently been described.(Bizet et al., 2015) Affected patients had only mildly disturbed ciliary morphology but an over-stabilised microtubule cytoskeleton and the authors proposed that defective delivery of protein complexes to cell junctions and cell membranes leads to impaired polarity, differentiation and degeneration of the renal tubular epithelium.(Bizet et al., 2015) In another study, *nphp4* knockdown in *Xenopus* epidermis disrupted the subapical actin cytoskeleton impairing communication with ciliary basal bodies and motile cilia function.(Yasunaga et al., 2015) Nephrocystin and nephrocystin 2 also interacts with beta-tubulin.(Otto et al., 2003) In the demonstration of disease mechanisms for IFT140 which are well established for other NPHP genes, we demonstrate how the cumulative examination of further NPHP genotypes using organoid modelling might better illustrate the common and/or distinguishing pathways mediating NPHP disease. Additionally, the ToppGene Human Phenotype output of *Vitreoretinal Degeneration* closely resembled the patient's non-renal phenotype, validating the fidelity of the disease model and differential expression analysis.

Existing research on renal ciliopathies suggests epithelial dysfunction as the cause of disease, (Braun and Hildebrandt, 2016) hence the epithelial component of the organoids were purified and examined. As a multicellular three-dimensional disease model, any segment of the nephron or non-epithelial cell type could be isolated from differentiated tissue using this method depending on the disease in question and the

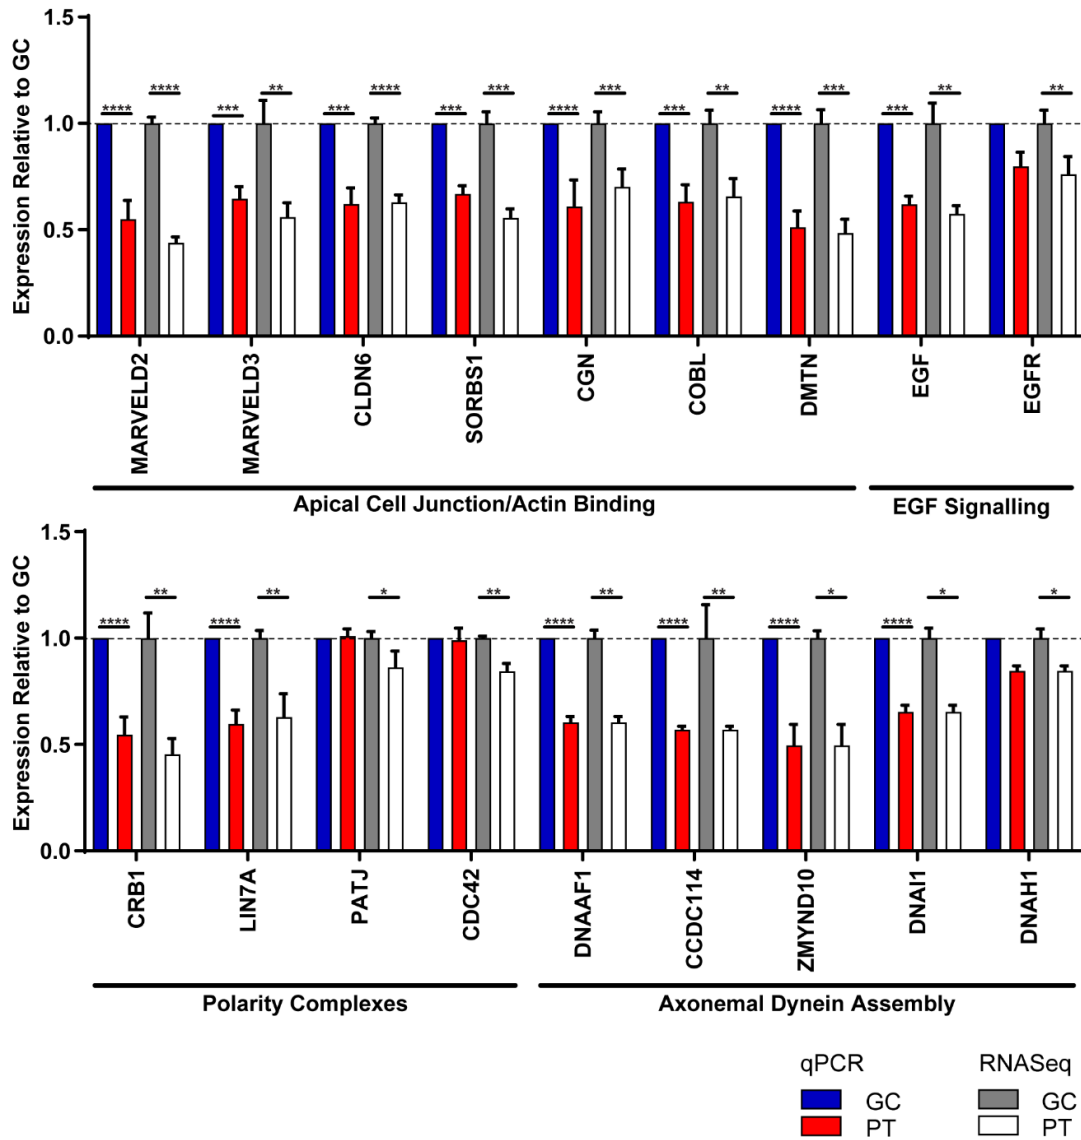

Figure 3.12 Validation of RNA Sequencing by qPCR

Quantitative real-time PCR (qPCR) of selected genes from RNA sequencing dataset. Genes were selected on the basis of adjusted *p* value and magnitude of read counts. For qPCR samples (GC blue; PT red) all PT values are graphed as 2^{-ddCT} and adjusted *p* values calculated by *t* test with Bonferroni-Dunn correction for multiple comparisons. For RNA sequencing samples (GC dark grey, PT light grey), all values were normalised to mean GC count and adjusted *p* values represent those from original bioinformatics analysis. (error bars represent standard error of the mean, * indicates adjusted *p* < 0.05, ** indicates adjusted *p* < 0.01, *** indicates adjusted *p* < 0.001, **** indicates adjusted *p* < 0.0001).

availability of an antibody for a specifying cell surface marker. The ability to fractionate different cell types from the organoids could theoretically illustrate the differential contribution of each cell type to the disease pathobiology. For example, the interstitial expansion seen *in vivo* in NPHP raises the possibility of stromal contribution to disease pathobiology.(Slaats et al., 2016) Whilst a stromal element of the organoid exists(Takasato et al., 2015), it is yet to be sufficiently characterised as renal stroma and as such was not studied in this work.

In this report, the study of a previously validated genotype directed the assays performed (e.g. ciliary number, length and morphology). In any future study of a previously unvalidated VUS, such guidance may not be available and the most appropriate assay may not be obvious. This raises the prospect of false negatives and false positives. The use of isogenic lines and normalisation for highly variable genes will be important to remove false positives. With respect to false negatives in the case of NPHP, a number of cell-line based functional genomic studies in this field have added pathway agonists (e.g. hedgehog modifiers, forskolin) to amplify readouts of dysfunctional molecular pathways(Hynes et al., 2014, Srivastava et al., 2017b, Booij et al., 2017). While this may also be applicable in organoids, it is not known whether such treatments would alter patterning rather than reveal a relevant disease response. Indeed, even using cell lines to model NPHP, it is not known whether this ‘stress’ pushes the model beyond the boundary of what remains relevant to the original disease or patient. Hence this is not a unique challenge to organoids. What we do demonstrate here is the application of an unbiased quantitative approach to the evaluation of cilia morphology. This approach could be applied to other NPHP models and further development could integrate machine learning to support a fully automated high-throughput assay for the purposes of patient specific compound screening without the need to dissociate the regenerated tissue.

The application of kidney organoids to the *in vitro* modelling of other types of inherited kidney disease raises specific challenges with respect to the disease studied. The transcriptional profile of the organoid derived by our protocol most closely resembles trimester 1 human fetal kidney.(Takasato et al., 2015) This suggests that diseases with antenatal or infantile disease onset (e.g. congenital nephrotic syndrome [OMIM: 256300]; autosomal recessive polycystic kidney disease [OMIM: 606702]) may be more readily

studied, compared to those with adult onset (e.g. autosomal dominant polycystic kidney disease [OMIM: 601313]). Without a patent vasculature, urinary drainage system or urine production, modelling of congenital anomalies of the kidney and urinary tract, or glomerulopathies such as inherited nephrotic syndrome and Alport Syndrome [OMIM: 301050, 203780], is less feasible. Prenatal, and hence low, expression of electrolyte channels and transporters may also limit the modelling of some tubulopathies. However, improving the degree of cellular maturation of the organoid model by refining culture conditions and introducing flow (Homan et al., 2016, Jansen et al., 2015, van den Berg et al., 2018) will likely expand the repertoire of kidney diseases amenable to disease modelling using iPSC derived models.

This study demonstrates that kidney organoids derived from patient iPSC are capable of expressing an inherited developmental renal disease phenotype. Together with CRISPR/Cas9 mediated gene-correction, kidney organoids represent a novel functional genomic platform for the validation of novel genomic variants. This study also demonstrates the study of human renal disease via a patient-derived, three dimensional, *in vitro* model. The fidelity of transcriptional profiling to identify not only established *IFT140* disease mechanisms but also those implicated for other NPHP genes heralds the ability to refine the common cellular pathways in NPHP through the future study of other known and novel genotypes. This study was enabled via coordinated clinical and laboratory research arms able to provide a comprehensive clinical and research genomic service for the rapid identification of novel VUS in a patient-specific disease model. The future applications of kidney organoids as a disease model may include high-throughput personalised therapeutic screening which could feed back to the patient within such a multidisciplinary clinical/experimental team approach.

Chapter 4 An unsuccessful attempt to validate a novel gene for nephronophthisis using patient-iPSC-derived kidney organoids.

4.1 Introduction

In Chapter 3, we demonstrate the capacity of patient-iPSC-derived kidney organoids to express a compound heterozygote *IFT140* disease phenotype consistent with that seen in previously published *IFT140* mutant models. Having established a set of protocols and assays optimised and validated to examine epithelial dysfunction as a model of NPHP, we then attempted to identify a novel gene for another patient with a genetically undiagnosed infantile NPHP phenotype.

In Australia, the KidGen Renal Genetic Collaborative has established a database of patients who remain undiagnosed following whole exome or genome sequencing. Established in 2016, KidGen is a consortium of nephrologists, geneticists, genetic counsellors and research scientists with a view to forwarding the genetic understanding of kidney disease.(Kidgen, 2017, Mallett et al., 2017) Patients are assessed in dedicated

renal genetics clinics and offered diagnostic targeted exome or genome sequencing where appropriate.(Mallett et al., 2016, Mallett et al., 2017, Jayasinghe et al., 2019) Patients with non-diagnostic sequencing results are referred for research level whole exome or genome sequencing analysis.

In the following chapter, a female proband with an infantile presentation of CKD resembling NPHP is identified carrying a homozygous VUS in *DNAH5*. This patient is prioritised for modelling in iPSC derived kidney organoids with a focus on testing the hypothesis that the *DNAH5* variant is causative of the disease phenotype. *DNAH5* is an axonemal dynein heavy chain which contributes to the interlinking outer dynein arm between the microtubule pairs of motile cilia.(Olbrich et al., 2002) Mutations in *DNAH5* are an established cause of Primary Ciliary Dyskinesia Type 3 (PCD3; [OMIM 608644]). As previously mentioned, the term ‘primary’ in this case is intended to imply a congenital dysfunction of the *motile* cilium (ie. not acquired or secondary) rather than to describe any problem with the primary (ie. non-motile) cilium. Individuals with PCD3 may present with *situs inversus* due to impaired nodal ciliary motility, recurrent respiratory tract infections and chronic suppurative lung disease due to impaired mucociliary clearance of airway sections, and infertility in males due to immotile spermatozoa.(Olbrich et al., 2002, Omran et al., 2000b, Faily et al., 2009, Knowles et al., 2013) PCD3 is not classically associated with any renal phenotype.

This project was ultimately unsuccessful in validating this *DNAH5* variant as causative of kidney disease for this proband using the kidney organoid model, as were our collaborators who modelled the variant in mice. This project highlights the importance of the variant curation process in the selection of appropriate candidate variants to model with kidney organoids and the need for revision of the novel gene validation thresholds for our laboratory moving forward.

4.2 Acknowledgements

In this project, Dr Catherine Quinlan phenotyped the proband, genome sequencing was performed by Dr Cas Simons (MCRI), isolation of peripheral blood mononucleocytes and iPSC reprogramming was performed by the iPSC Core Facility (MCRI, Dr Katerina Vlahos) and gene correction of the iPSC performed by the Gene Editing Core Facility

(MCRI, Dr Sara Howden). Post-immunofluorescent analysis scripts for ciliary morphology and cyst culture analysis were written by Dr Kynan Lawlor.

4.3 Methods

4.3.1 Genome Sequencing and Analysis

Ethics approvals, exome sequencing and analysis pipelines were performed using the same methods described in Chapter 3.5.1.

4.3.2 Reprogramming and Gene Correction of iSPC

In contrast to the simultaneous reprogramming and gene correction protocol described in Chapter 3.5.2, we were unable to sample patient fibroblasts and thus employed a two-step protocol reprogramming iPSC from patient peripheral blood mononuclear cells (PBMC) followed by gene correction of reprogrammed patient iPSC.

Using density gradient centrifugation, PBMC were isolated from a patient blood sample and cultured in erythroid expansion medium (Stem Cell Tech; Cat# 09605 & 02692) for 7 days, with alternate daily media changes. At day 7, 500×10^3 PBMCs were pelleted and re-suspended in erythroid expansion medium containing Sendai virus (Life Tech; Cat# A167517) with MOIs of 5, 5, and 5 (i.e., KOS MOI = 5, hc-Myc MOI = 5, h-Klf4 MOI = 5) and polybrene (4 ug/ml) to final concentration of 500×10^3 cells/ml. Cells were then plate in one well of a 12-well plate and centrifuged at 2000 rpm for 30 minutes at room temperature.

Sendai virus was removed at 24 hours by centrifugation of the cell and virus suspension at 300g for 5 minutes and resuspension in fresh erythroid expansion medium and returning the cells to the original well. Three days following transduction, cells were plated onto irradiated mouse embryonic fibroblasts in 1:1 mix of StemSpan SFEM II (Stem Cell Tech; Cat #09605) and hiPSC media. On day 5 additional human iPSC media was added. On day 7 all media was aspirated and refreshed with human iPSC media, changed daily until colonies were able to be selected (around three weeks post-transduction).

4.3.3 Cell Culture and Directed Differentiation to Kidney Organoids

Undifferentiated iPSC were maintained in feeder free conditions on hESC qualified Matrigel in E8 media (STEMCELL Technologies). The originally published organoid protocol was optimised in APEL media, however this media was withdrawn by its manufacturer and replaced with APEL2. Having experienced some difficulty in reproducing our kidney differentiations in APEL2, the laboratory made a decision to switch to TeSR Essential 6 (E6, STEMCELL Technologies) base media as a fully defined, low-cost media which could be easily made in-house in the context of any future supply difficulties.

One day prior to differentiation, iPSC were dissociated from 60-70% confluence with TrypLE (Thermo Fisher) and plated at 7.5×10^4 cells per cm^2 in a 6 well plate coated with hESC qualified Growth Factor Reduced Matrigel (BD Biosciences) in 2.5mL E8 media supplemented with Revitacell (Thermo Fisher). The following morning, cells were treated with 6-8 μM CHIR99021 in E6 basal media (STEMCELL Technologies) for 3-5 days, followed by FGF9 (200ng/mL) and heparin (1 $\mu\text{g}/\text{mL}$) for 2-4 days, changing media every day. Cell monolayers were dissociated to a single cell suspension using TrypLE Select (Thermo Fisher) on day 7 and resuspended in 5 μL TeSR-E6 media per million cells. Cells were bioprinted as previously described.(Higgins et al., 2018) The dissociated cell suspension was aspirated into a sterilised 100 μL Gastight syringe (Hamilton) with a 21-gauge Removable Needle (Hamilton) and loaded onto the NovoGen MMX bioprinter (Organovo) before printing 8 x 4 mm lines of cells onto 0.4 μm polyester membrane 6 well Transwell inserts (CLS3450 Corning Costar). Organoids were cultured over E6 with 5 μM CHIR 99021 for 1 hour to induce nephrogenesis. Organoids were then cultured over E6 supplemented with FGF9 (200ng/mL) and heparin (1 $\mu\text{g}/\text{mL}$) for five days, followed by all *trans* retinoic acid (2 μM) and Antibiotic-Antimycotic (0.5x) for 2-4 days. Transwell culture continued in E6 supplemented with Antibiotic-Antimycotic (0.5x, Invitrogen) and no added growth factors for 11 days changing media three times a week.

4.3.4 Immunofluorescent Analysis

Organoids were fixed in 2% paraformaldehyde for 20 mins on ice and washed with PBS. Whole organoids were cut from the Transwell filter and blocked/permeabilised for at least 3 hours in 10% Donkey serum/0.3% Triton X/PBS. Both primary and secondary

antibodies were incubated overnight at 4 degrees and washed with 0.3% Triton X/PBS. Whole mounts were mounted into MatTek glass bottom dishes and cleared with 90% glycerol. Images were obtained with an Andor Dragonfly Spinning Disk confocal microscope.

4.3.5 *Ciliary Analyses*

Ciliary length was measured manually from Z stack images in ImageJ (version 1.51n). Image file names were shuffled and blinded. Segmented lines were traced over cilia and measured using the ROI Manager tool and Measure analysis functions. Cilia crossing the boundary of the image (ie. not fully captured in the Z stack) were not included. Proportions were compared using chi-squared contingency tests in GraphPad Prism (version 7.04).

Ciliary morphology was assessed in using a similar protocol to that described in Chapter 3.5.5. Ilastik 1.3.2 (Berg et al., 2019) was used to classify voxels as belonging to cilia or background based on manual annotation of a subset of regions. Classification probability maps were processed using the scikit-image 0.15 python library.(van der Walt et al., 2014).to import each image, perform Gaussian blurring (Sigma : x = 0.8, y= 0.8, z = 0) and assign labels to regions with pixel value greater than 0.6. These regions mainly represented cilia and were processed to generate sets for visual scoring based on the previously described method (Forbes et al., 2018) except that objects with area less than 200 voxels were excluded.

4.3.6 *Magnetic Associated Cell Sorting (MACS) and Cyst Culture*

MACS and Matrigel cyst culture was performed in an 8 well chamberslide using the same protocol as reported in Chapter 3.5.7. Following fixation and immunofluorescent staining the entire chamberslide well was imaged for both genotypes with an Andor Dragonfly Spinning Disk confocal microscope. Using a protocol analogous to the ciliary morphology protocol, ECAD+ cysts were filtered from these raw images using a Fiji script. 280 ECAD+ structures were isolated from the combined data set and presented as 3-dimensional tiff files with 4 isolated channels. Cysts were shuffled and blinded to genotype for assessment. Each cyst was manually categorised with regards to the apical distribution of ZO-1 and/or F-actin expression (polarised, non-polarised, indeterminate)

Proportions were compared statistically in GraphPad Prism (version 7.01) using Fisher's exact test.

For cysts where the basolateral boundary of the cyst did not cross the border of the isolated image, the outline of a maximum intensity projection of the ECAD signal was manually traced with the polygon selection tool. The perimeter, area and maximum diameter was then calculated using the Measure function of ImageJ. Proportions were compared statistically in GraphPad Prism (version 7.01) using students *t* test and Bonferroni adjusted Type 1 false discovery rate of 1% (ie. $p < 0.01$) for multiple comparisons.

4.3.7 *qPCR*

cDNA synthesis and qPCR was performed according to the protocol outlined in Chapter 3.5.6.

4.3.8 *Isolation and Culture of Human Urine Derived Renal Epithelial Cells*

Human urine derived renal epithelial cells (HURECs) were isolated according to a published protocol by Zhou et al. (Zhou et al., 2012) At least 50mL of fresh urine was centrifuged at 400g for 10 minutes at room temperature. The supernatant was aspirated down to 1mL of urine and the pellet resuspended. The cell suspension was then washed in 10mL chilled PBS supplemented with Primocin (Invivogen). The sample was then centrifuged at 200g for 10 mins. The supernatant was aspirated and the pellet resuspended in 1mL primary medium[†] and transferred to a 12 well plate coated with Laminin-521. Another 1mL of primary media was added and cells were cultured overnight at 37°C, 5% CO₂. For the next three days, 1mL of media was added each day (no media was removed). On the fourth day 3mL of media was aspirated with a P1000 and 1mL proliferation media (1:1 RE media[‡]:MC media[§]) was added. Each subsequent day 1mL of media was removed

[†] 100mL primary medium = 45mL high glucose DMEM (Hyclone) + 45mL Ham's F12 (Invitrogen) + 10mL FBS (Interpath Services) + 200µL Primocin (Invivogen) + 700µL combined REGM SingleQuots (Lonza)

[‡] 100mL RE media = 100mL REBM Renal Epithelial Growth Basal Media (Lonza) + 700µL combined REGM SingleQuots (Lonza) – combined and filtered using 0.2µm filter unit.

[§] 100mL MC media = 90mL high glucose DMEM (Hyclone) + 10mL FBS (Interpath Services) + 1mL Glutamax (Invitrogen) + 1mL non-essential amino acids (Invitrogen) + 0.5µg bFGF (Lonza) + 0.5 µg EGF (Peprotech) + 0.5ug PDGF-AB (Peprotech), – combined and filtered using 0.2µm filter unit.

from the well and 1mL fresh proliferation media was added. Once colonies of proliferating epithelial cells were observed, they were dissociated with Trypsin-EDTA 0.05%, inactivated with FDMEM (high glucose DMEM + 10% FBS + 1x Glutamax + 1x NEAA + 1x antibiotic/antimycotic) and replated to a fresh, uncoated well of a 12 well plate in fresh proliferation media. Cells were passaged at 80-90% confluence to 100-150x10³ cells/well of a 6 well plate.

In preparation for immunofluorescence cells were cultured on sterilised 15mm diameter glass coverslips. In a Class II Biological Safety Cabinet, coverslips were briefly immersed in 80% ethanol and then, held with sterilised pincers, briefly dried in the air flow of the cabinet before immersing in DPBS. Three coverslips were transferred to each well of a 6 well plate and dissociated cells were seeded over the top and allowed to culture to confluence before in-well fixation.

4.4 Results

4.4.1 *A case of genetically unresolved infantile nephronophthisis.*

The proband (RG1005.213) was born premature at 32 weeks gestation. Her mother had undergone amniocentesis and chromosomal microarray at 20 weeks gestation because of echogenic bowel and consanguineous parentage.(Figure 4.1A) This demonstrated no genomic imbalances but long continuous stretches of homozygosity. Later in the pregnancy RG1005.213 was found to have oligohydramnios and was born with contractures and pulmonary hypoplasia but with a normal urine output and renal function. A renal ultrasound, however, demonstrated enlarged, echogenic kidneys which later developed punctate foci indicative of renal microcysts.(Figure 4.1B) She exhibited mildly delayed growth and development but an MRI of her brain was normal, importantly excluding the molar tooth sign of the midbrain associated with Joubert syndrome.(Figure 4.1C)

At four years of age she was assessed by a geneticist and was felt to have facial dysmorphic features inconsistent with her parents' appearances. This included a flat facial profile, epicanthic folds, prominent corneas, short nose, long philtrum and broad thumbs without polydactyly. A liver ultrasound revealed coarsened and heterogeneous

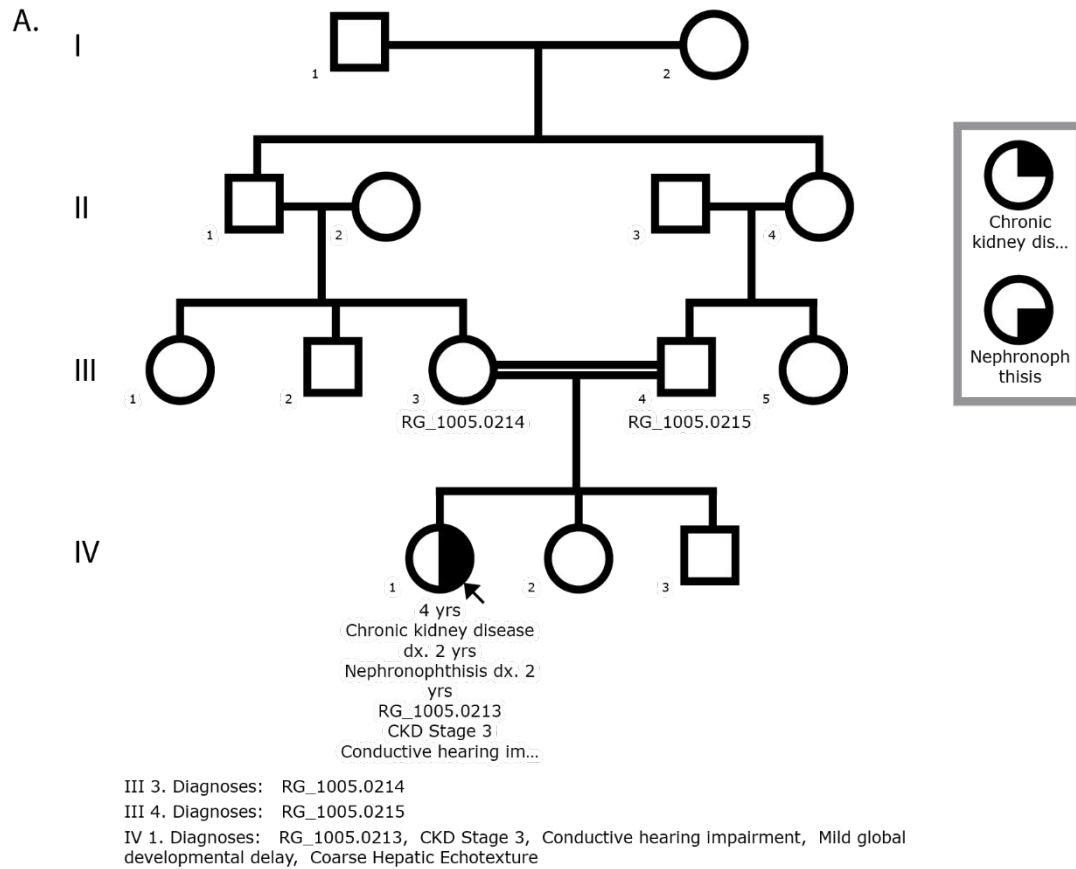

Figure 4.1 Clinical information regarding RG1005.213
(A) Pedigree/genogram for RG1005. (B) Ultrasound of right kidney at 7 years old demonstrating generalised hyper-echogenicity of the kidney (between 'A' callipers) and numerous medullary punctate foci suggestive of micro-cysts. The coarsened echotexture of the liver can be seen above and to the left of the kidney. (C) MRI Brain demonstrating normal midbrain without molar tooth sign of Joubert Syndrome.

echotexture without any focal hepatic lesions. Audiology testing has found mild sensorineural hearing loss and ophthalmology review has identified no significant ocular phenotype.

Importantly, her diagnosis of NPHP had been made on clinical grounds, without tissue biopsy of the kidney or liver. This is broadly the international standard of care for such cases where in the absence of any available treatment beyond the palliation of CKD, the risk of an invasive test cannot be justified.

RG1005.213 is the oldest of three children to consanguineous parents of Lebanese descent with no notable family history of kidney or other inheritable disease.(Figure 4.1A) Her parents are first cousins and her siblings are healthy. She is currently eight years old and has CKD stage 3 with an estimated GFR of 45 ml/min/1.73m².

After consultation and genetic counselling with the KidGen Renal Genetics clinic, RG1005.213 underwent whole exome sequencing targeting ciliopathy and cystic kidney disease gene lists which was non-informative.

4.4.2 *Novel variant curation prioritises DNAH5 as a gene of interest.*

Given the inheritance pattern illustrated by the pedigree and the consanguinity of her parents, homozygous variants were prioritised in the analysis of the trio whole exome sequencing output.(Table 4.1) *DNAH5* c.9751G>C, p.Ala3521Pro was selected for functional modelling in kidney organoids.

DNAH5 c.9751G>C has a low allelic frequency in population databases and high aggregate damage scores.(Table 4.1) The p.Ala3521 displays very high amino acid conservation throughout vertebrates (Figure 4.2) and is positioned in an alpha helix domain in the stalk of the protein. *DNAH5* is expressed in kidney tissue. Olbrich et al. performed Northern blot analysis on mouse tissue and demonstrated the strongest bands in lung and kidney, ahead of brain, heart and testis.(Olbrich et al., 2002) Pathogenic variants in *DNAH5* have an established human phenotype in PCD3 for which no renal phenotype is established. The RG1005.213 proband does not manifest any clinical evidence of a motile ciliary deficit (ie. dextrocardia, chronic suppurative lung disease).

Genomic Position	Gene Name	Change	Predicted Consequence	Max AF	Damage Score

Table 4.1 Prioritised homozygous variants for RG1005.213 following trio whole exome sequencing

Max AF indicates the maximum allelic frequency documented in any subpopulation of the ExAC or 1000G databases.

Damage Score is a rudimentary aggregate damage score essentially provides the number of damage prediction algorithms that predict the variant to be damaging, pathogenic or likely pathogenic. Algorithms include: SIFT, Polyphen, LRT, MutationTaster, MutationAssessor, FATHMM, PROVEAN & CADD.

Figure 4.2 Interspecies amino acid conservation for *DNAH5* and *KDM8* variants

WORM: *Trichinella spiralis*, CORAL: *Stylophora pistillata*. Generated by Uniprot, <https://www.uniprot.org/>

However, the vast majority of clinically reported *DNAH5* variants affect premature termination or frameshift of the protein (Olbrich et al., 2002) and it is possible that more subtle variants could produce alternative phenotypes. The ENU derived *Dnah5*^{b2b1003Clo} homozygous mouse phenotyped by the Jackson Laboratory illustrates kidney cysts and duplication in addition to *situs inversus* and immotile respiratory cilia. (<https://www.jax.org/strain/013684>, accessed 8th October 2018) Of relevance, *DNAH5* was significantly differentially downregulated in the DGE analysis performed for the *IFT140* modelling project. (Forbes et al., 2018) It was hypothesised that *DNAH5* c.9751G>C variant kidney organoids would demonstrate similar abnormalities in ciliary morphology, cyst culture and gene expression, to that seen in the *IFT140* project.

Considering this information, a decision was made to validate this variant in both kidney organoids and mice. As no foreseeable clinical opportunity to collect a skin biopsy from the patient existed, iPSC were reprogrammed from patient PBMC by the MCRI iPSC Core Facility. These iPSC cells underwent gene correction for the NM_001369.2:c.9751G>C variant by the MCRI Gene Editing Core Facility. Genotypes were validated by Sanger sequencing and, pluripotency was confirmed by flow cytometry and SNP microarray confirmed no major structural genomic imbalances. (Figure 5.11)

4.4.3 *DNAH5* c.9751G>C kidney organoids do not demonstrate abnormal ciliary morphology or polarisation defects compared to gene edited control.

The differentiation protocols were optimised for patient-derived and gene-corrected iPSC clones in E6 media. In order to determine the ideal CHIR duration for the iPSC, both clones were treated with each of three, four and five days of CHIR99021 during the cell monolayer phase of differentiation. (Figure 4.3a and 4.3b) Kidney organoid end point was validated by the presence of all four segments of the nephron by immunofluorescence. (Figure 4.4) Consistent with the original published protocol, longer relative CHIR exposure was associated with more proximally patterned nephrons, demonstrating the ability to alter the nephron patterning of the organoid by manipulating the relative time cultured in CHIR99021 versus FGF9 prior to dissociation. (Takasato et al., 2015) Paradoxically, for the patient iPSC clone, the greatest representation of ECAD⁺/GATA3⁺ epithelium was in the 5 day CHIR condition, forming a central, reticulated network linking the surrounding nephrons. (Figure 4.4) Whilst this is a

Figure 4.3a Optimisation differentiation experiment for *DNAH5* PT and GC iPSC clones
 The differentiation of the patient clone is pictured above. To establish the ideal differentiation conditions for each iPSC clone, duration of CHIR99021 treatment of the monolayer was varied between 3 and 5 days. The 3 day CHIR condition was subsequently treated with 4 days of FGF9 before dissociation and bioprinting, the 4 day CHIR condition with 3 days of FGF9, and so on. The remainder of the protocol continued as indicated. Whilst bright field images are able to illustrate the development of structures, in the absence of any inbuilt fluorescent reporter expression, bright field morphology is poorly predictive of nephron patterning. Scale bars 200 μ m.

Figure 4.3b Optimisation differentiation experiment for *DNAH5* PT and GC iPSC clones
The differentiation of the *DNAH5*-GC clone is pictured above. Scale bars 200 μ m.

Figure 4.4 Immunofluorescent validation of optimisation differentiation experiments at day 7+18

Glomeruli are stained with NPHS1 (white), proximal tubule is stained with LTL (blue), distal tubule is stained with ECAD (CDH1, green) and collecting duct is coimmunofluorescent for ECAD and GATA3 (green and red respectively). For both lines with increasing CHIR99021 duration, there is an increased representation of glomerular structures. Paradoxically the patient line 5 day CHIR organoids developed a network of ECAD+/GATA3+ epithelial tubules linking nephron structures. This has been observed previously and is not well understood.

morphology our laboratory has witnessed on previous occasion in other iPSC clones at higher CHIR concentrations, it is not understood how it arises. Whilst this would have been an ideal organoid for epithelial characterisation, the same condition from the gene-corrected iPSC clone provided the opposite extreme of nephron patterning. These organoids demonstrated dense NPHS1+ glomeruli and only few ECAD+/GATA3+ structures precluding a comparative analysis of tubular epithelium. (Figure 4.4) The 3 day conditions were selected for further analysis as they were the most similarly patterned paired differentiation, with acceptable and feasibly reproducible tubular representation.

Correction of the *DNAH5* c.9751G>C variant did not affect ciliary length or morphology in wholemount ECAD+ organoid tubules.(Figure 4.5A,B) The mean primary ciliary length within patient tubules (1.61 μm , SEM 0.02 μm , $n = 726$) was not different to that measured in gene-corrected tubules (1.62 μm , SEM 0.02 μm , $n = 800$; $p = 0.53$). An similar proportion of distal tubular cilia demonstrated a straight, wild type morphology in both PT (49.7%) and DNAH5-GC (48.8%) organoids.(Figure 4.5C) Indeed, an increased proportion of DNAH5-GC cilia revealed a clubbed morphology (26.0% vs 15.0%).(Figure 4.5C)

Matrigel cyst culture of EPCAM+ MACS sorted epithelial cells from both organoids did not reveal differences in polarisation or open lumen formation.(Figure 4.5D,E) The percentage of cysts demonstrating apical expression of ZO-1 and F-ACTIN was the same in patient and gene-corrected conditions (PT 80.00% vs GC 83.24%, $p = 0.46$). (Figure 4.5E) No difference in cyst size by cross-sectional area was evident between the genotypes (μ : PT 3877 μm^2 vs GC 3134 μm^2 ; $\Delta\mu$ 742, 95%CI -1.6 to 0.09; $n = 160$). (Figure 4.5F) There was a trend towards increased mean cyst perimeter (μ : PT 282 μm vs GC 247 μm ; $\Delta\mu$ -34, 95%CI -62 to -7) and maximum diameter (μ : PT 96 μm vs GC 85 μm ; $\Delta\mu$ -11, 95%CI -21 to -2) in the patient cysts compared to gene corrected. However the magnitude of difference was not felt to be significant, was in the opposite direction to that hypothesised and failed to reach statistical significance following adjustment of false discovery rate for multiple comparisons of co-dependent variables.(Figure 4.5G,H)

Figure 4.5 Ciliary analysis and epithelial cyst culture from PT and DNAH5-GC organoids (A) Ciliary morphology was examined by immunofluorescence for acetylated tubulin in ECAD⁺ regions of whole mount kidney organoids. (B) No difference was found in ciliary length between PT and DNAH5-GC organoids. (C) There was no difference in the proportion of cilia with wild type morphology. DNAH5-GC cilia had slightly higher proportion of clubbed cilia but fewer cilia of indeterminate morphology. (D) Matrigel cyst culture of MACS sorted epithelium demonstrated no difference in ECAD⁺ polarised cyst formation (E), cyst area (F), perimeter (G) or diameter (H). Error bars: standard error of mean. Scale bars as marked. Categorical variable assessed with chi squared test, continuous variables with unpaired t test.

4.4.4 *DNAH5 c.9751G>C kidney organoid epithelium does not demonstrate transcriptional abnormalities in axonemal dynein assembly.*

The original selection to model the *DNAH5* c.9751G>C variant was partly founded on the observation of downregulation of *DNAH5* in *IFT140* organoid epithelium compared to *DNAH5*-GC control. Using qPCR the transcriptional activity of other components of the axonemal dynein assembly pathway was compared in RNA lysates obtained from EPCAM+ MACS sorted epithelium from the PT and *DNAH5*-GC organoids. (Figure 4.6A) There was no evidence of differential downregulation of *DNAH5* or other dynein axonemal assembly genes (*DNAAF1*, *DNAH1*, *DNAH11* or *CCDC114*) between the two epithelial cell isolates. For completeness, qPCR was also examined for the other differentially expressed genes from the *IFT140* project. No significant difference in expression of polarity, EGF signalling or cell-junction component pathways was found. (Figure 4.6A)

Given the lack of evidence of differential gene expression between patient and gene corrected organoids, it was possible that *DNAH5* c.9751G>C was not the causative variant. As such, both patient and gene corrected lines would show an equivalent phenotype. To investigate this possibility, a non-isogenic, wild type control iPSC clone (CRL1502.3) was simultaneously differentiated alongside a paired differentiation of the patient and *DNAH5*-GC lines. Regrettably, technical difficulties precluded replication of qPCR for any gene within this three-way comparison besides *DNAH5* which was significantly downregulated in both PT and *DNAH5*-GC compared to non-isogenic control. With only one replicate from the non-isogenic control, it was not possible to perform statistics for other qPCR comparisons.

4.4.5 *KDM8 c.1219G>T is an alternative candidate genetic variant for RG1005.213*

The results thus far have been unable to establish a differential phenotype between *DNAH5* c.9751G>C variant organoids and a gene edited control. Simultaneously, a local collaborator had engineered a mouse model carrying the homozygous *DNAH5* c.9751G>C variant and has been unable to demonstrate a renal phenotype in post-natal mice up to 1 year of age. (Ian Smyth, personal communication)

B.

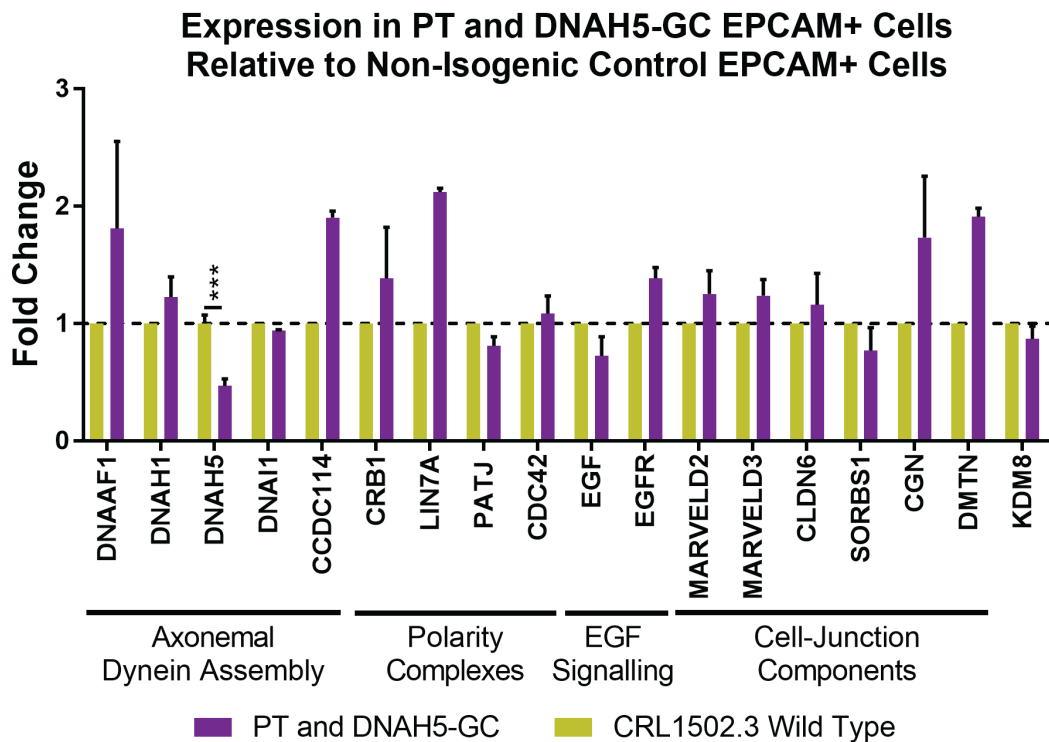

Figure 4.6 qPCR analysis of PT and DNAH5 EpcAM+ cells

(A) One of the reasons for selecting *DNAH5* for modelling was the fact it was downregulated in the IFT140 RNASeq dataset under the GO term Axonemal Dynein Assembly. No transcriptional difference in this set of genes or any other identified in the IFT140 project was observed between PT and DNAH5-GC cells. (B) An attempt to transcriptionally compare the combined PT and DNAH5-GC EpcAM together to a non-isogenic control demonstrated upregulation of these some of these genes by interpretation was limited by technical difficulties.

Considering the likelihood that the *DNAH5* c.9751G>C variant is not associated with RG1005.213's phenotype, the exome sequencing variant list was re-examined in an attempt to prioritise another potential variant. RG1005.213 carries a homozygous c.1219G>T variant in *Lysine demethylase 8 (KDM8)*; also known as 'Jumonji-C domain containing protein 5' or *JMJD5*; OMIM: 611917). This variant is predicted as moderately damaging by all *in silico* programs used by the database (includes SIFT, M-CAP, Polyphen, LRT, MutationTaster, PROVEAN and CADD) and shows a low (but not rare) allelic frequency in the ExAC and 1000 genome databases of 0.003. The GnomAD database reports a single homozygous individual with no documented phenotype. Unlike *DNAH5*, no existing human phenotype is associated for pathogenic variants in *KDM8*. *KDM8* is expressed in the epithelial bulk RNA sequencing datasets from the IFT140 project (without differential expression between patient and control) and in our laboratory's wild type organoid single cell RNA sequencing database (data not shown). The affected amino acid is conserved throughout vertebrates to nematode and coral.(Figure 4.2)

KDM8 is a putative tumour suppressor gene. The protein acts in a complex with *RCCD1* as a histone H3 lysine demethylase epigenetically regulating genes controlling cell cycle progression.(Ishimura et al., 2012, Marcon et al., 2014) During mitosis *KDM8* colocalises at the mitotic spindle, increasing microtubular stability by α -tubulin acetylation and interkinetochore tension, satisfying the spindle assembly checkpoint, necessary to complete mitosis.(He et al., 2016) *KDM8* interacts with the DNA binding domain of p53, negatively regulating its activity explaining why p53 transcriptional target gene *Cdkn1a* expression is upregulated in both *KDM8* knockout mouse and cellular models.(Ishimura et al., 2012, Huang et al., 2015) Mouse embryonic fibroblasts collected from embryos carrying a hypomorphic *KDM8* allele demonstrated severely reduced proliferation rate, which was rescued by siRNA knockdown of *Cdkn1a*.(Ishimura et al., 2012) Knockdown of either *KDM8* or *RCCD1* in HEK293 cells resulted in abnormal mitotic figures characterised by supernumerary centrosomes, disorganised multipolar spindle assembly and multidirectional chromosome segregation.(Marcon et al., 2014) Wu et al additionally localised *KDM8* to the cell cytoplasm and established a role for microtubule stabilisation by regulation of MAP1B protein levels.(Wu et al., 2016) In this study, siRNA knockdown in HeLa cells decreased acetylation and dephosphorylation of cytoplasmic α -tubulin, and

H2AX increased cell sensitivity to microtubule destabilisation agents.(Wu et al., 2016) Finally, *KDM8* siRNA knockdown in differentiated *in vitro* osteoclasts produced accelerated osteoclastogenesis by a reduced protein hydroxylation of NFATC1, a key osteoclastogenic transcription factor.(Youn et al., 2012)

There exists a number of similarities between *KDM8* function and other established NPHP-associated genes. Firstly, its association with mitotic spindle poles during mitosis is shared by MAPKBP1, a non-ciliary protein recruiting to the mitotic spindles poles during mitosis and associated with increased DNA damage response by γ H2AX immunofluorescence in patient fibroblasts and renal biopsies samples.(Macia et al., 2017) A recent report from Bizet et al highlighted a role for IFT52 in the regulation of cytoplasmic microtubule stabilisation through interaction with MAP4 (Bizet et al., 2015), and this represents another proposed *KDM8* function.(Wu et al., 2016)

Whilst the literature suggests embryonic lethality in the setting of *KDM8* variants, most of the current literature on *KDM8* has been performed with siRNA knockdown or knockout models, raising feasibility that a hypomorphic missense variant could be associated with a more mild human disease phenotype.

D7+18 patient organoids were examined by whole mount immunofluorescence for phosphohistone H3. Repeated examination was unable to find any pHH3+ figures in either patient or DNAH5-GC tubules despite the regular appearance of normal appearing mitotic figures in the stromal regions of the organoids.(data not shown) When compared to non-isogenic control, *KDM8* transcription was similar between non-isogenic control, patient and DNAH5-GC epithelium.(Figure 4.6)

4.4.6 *An attempt to utilise primary patient urine derived cells to validate KDM8 as a candidate variant, ahead of commitment to organoid modelling.*

The gene correction of a second candidate variant in a patient iPSC cell line and the subsequent differentiation experiments represented a significant investment of time and money. Human urine derived renal epithelial cells (HURECs) are painless to collect and represent a straightforward approach for obtaining primary renal cellular material from

Figure 4.7 Culture of primary HURECs
 (A) Bright field images taken during culture of HURECs from urine samples from patient, mother and father. (B) HURECs from all subjects were negative for ECAD and ZO1. (C) HUREC cultures were negative for EPCAM but positive for PAX2. Cell cultures were low in confluence and may improve epithelial marker expression at higher confluence. Scale bars 50 μ m.

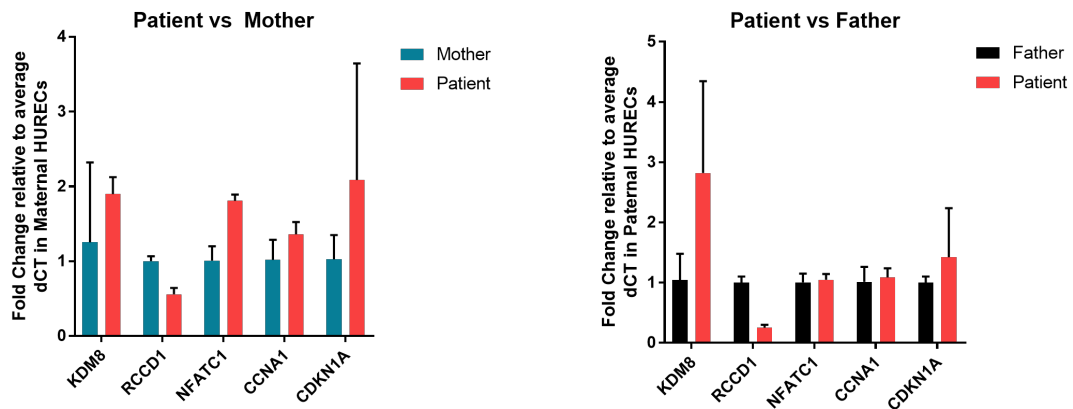

Figure 4.8 qPCR of HUREC cultures
 Lysates were generated from two separate HUREC cultures. *KDM8* expression appears higher in patient HURECs than for either parent. *RCCD1* expression appears lower. *CDKN1A* expression was variable. None of the changes were statistically significant. (n = 2, students t test).

patients for preliminary functional genomic modelling or iPSC reprogramming.(Zhou et al., 2012) In an attempt to develop supporting evidence for the pathogenicity of the *KDM8* variant prior to further iPSC gene editing we cultured HURECs from patient and both parental urine samples.

All urine samples gave rise to cell colonies which proliferated at similar rates and appeared morphologically consistent to images presented in the Zhou et al. (2012) protocol.(Figure 4.7A) Bulk RNA sequencing of the patient HURECs (not the parental HURECs) was performed by a collaborating laboratory as part of a mutually exclusive project. This did not reveal any obvious qualitative canonical splicing abnormalities in any of the genes of interest, including *DNAH5* and *KDM8*.(Cas Simons, personal communication) Immunofluorescence of all lines was disappointingly negative for epithelial antigens including EPCAM, ECAD and ZO1 (Figure 4.7B,C), however this may reflect the low confluence of the cultures used for immunostaining. All lines demonstrated nuclear expression of PAX2 which would suggest a renal epithelial origin.(Figure 4.7C) qPCR of HUREC RNA lysates provided variable results that failed to reach statistical significance.(Figure 4.8)

Differential *KDM8* protein expression between patient and parental HUREC lysates by SimpleWes capillary Western blot was unable to be reproducibly optimised prior to thesis submission but will be pursued as a potential means of prioritising this alternative genetic variant.

4.5 Discussion

This chapter describes an unsuccessful attempt to validate *DNAH5* c.9751G>C as a novel genotype for presumed NPHP. There are a number of factors that may have contributed to this negative finding. One probability is that *DNAH5* c.9751G>C is not the variant responsible for the renal disease in RG1005.213, which would suggest a need to optimise variant selection methods and thresholds. It is also possible that the variant was correct but the organoid assays performed were not of sufficient fidelity to demonstrate it. In spite of the lack of success in validating a variant for this pedigree, there are a number of learning points from this project which stand to improve our approach to prospective disease modelling projects.

Once believed to be a distinct disorder, NPHP is now understood to be a heterogeneous group of disorders with a broad genetic underpinning. (Braun and Hildebrandt, 2016) In clinical practice, renal biopsy is rarely performed in NPHP because the procedural risk of the biopsy procedure is greater than any benefit derived from a histological diagnosis, given there is no targeted treatment available. Accordingly it is well outside the scope of ethical genomic research to pursue such a procedure if it will be purely for academic benefit. This creates a challenge for research focused on novel gene discovery based entirely on an individual patient. RG1005.213 is presumed to have a diagnosis of NPHP on the basis of likely autosomal recessive inheritance, echogenic kidneys with evidence of microcystic change on ultrasound, a coarsened liver echotexture and soft facial dysmorphic features. However, there is no histological phenotype for this case and it is plausible that a biopsy could demonstrate segment specific features that may have directed alternative lines of inquiry within the organoid model. This project was approached assuming a distal tubular or pantubular pathology, an assumption that may have been incorrect. It is even plausible that RG1005.213 suffers from a non-ciliary renal dysplasia on the spectrum of congenital abnormalities of the kidney and urinary tract (CAKUT). Whilst one clear prospective benefit of diagnostic sequencing for renal disease is the ability to make a diagnosis without renal biopsy, it is possible that with an increasing understanding of the heterogeneity of diseases like NPHP, deep histological phenotyping could play an active role in characterising disease and directing functional genomic analyses in patients referred for research genomics.

Assuming that the definitive phenotype for RG1005.213 is NPHP, one could reasonably argue it was ambitious to attempt to redefine a novel phenotype for a gene with an already strongly associated phenotype, as PCD3 is for *DNAH5*. Whilst rare, the association between motile and non-motile ciliopathy is described. Mutant mouse models of *INVS/NPHS2* demonstrate reduced ciliary beating frequency and angle in respiratory cilia. (Tsuji et al., 2016) Similarly, a patient with tracheal motile ciliary dyskinesia and NPHP associated with a truncating variant in *IVNS/NPHP2* has been described. (Moalem et al., 2013) Variants in *CCDC114* previously associated with isolated PCD (Knowles et al., 2013) have recently been described in patients with comorbid renal dysplasia and sensorineural hearing loss. (Li et al., 2019) A recent, unpublished, local study of motile cilia function in patients with genetically proven NPHP has identified subtle slowing of

ciliary beat frequency and increased mean ciliary deviation. (Phil Robinson & Catherine Quinlan, personal communication). Taken together this evidence suggests a less mutually exclusive clinical phenotype between primary and motile ciliopathies than previously thought, which is not surprising given the profound ultrastructural similarities between the two types of cilia. Given the rarity that a mutually exclusive phenotype is presented for a gene with an established link to a monogenic disease, pursuing such a scenario in the future is likely to be of similarly low yield.

Published research describing novel Mendelian gene discovery for NPHP has frequently involved positional cloning, linkage analysis and/or homozygosity mapping across multiple unrelated individuals with a similar genotype and phenotype. (Hildebrandt et al., 1997, Haider et al., 1998, Mollet et al., 2002, Sayer et al., 2006, Otto et al., 2010) By comparison to most established international renal genomic databases, the KidGen research genomics database is young. Having collected prospective data from genetically unresolved patients for only 5 years, this database is unlikely to contain multiple unrelated patients with collective variants in ultra-rare disease genes. Therefore, collaboration with more established databases as well as international genotype matching programs such as Matchmaker Exchange (<https://www.matchmakerexchange.org/> accessed 24/09/19), will be paramount to our group's ability to identify multiple affected families affected by our candidate genotypes prior to investing in organoid modelling projects. We have inquired with an international collaborator who was unable to find any homozygous variants in *KDM8* in a database of around 400 unsolved NPHP probands.

A major aspect of the decision to model the *DNAH5* c.9751G>C variant was the observation of transcriptional downregulation of *DNAH5* in the IFT140 project DGE analysis. This would not be the first cytoplasmic dynein motor protein described to interact with an IFT protein. DNAAF1 [OMIM 613190] is dynein motor assembly protein typically associated with Primary Ciliary Dyskinesia Type 13 that displays variable cardiac phenotype and interacts with IFT88 for its proper function. (Hartill et al., 2018) Because of the link to the IFT140 transcriptional profiling, we hypothesised that the same set of assays would demonstrate differential results. However, no difference was observed in ciliary length or morphology between iPSC-derived PT and *DNAH5*-GC organoid epithelium. This would suggest that the transcriptional downregulation of *DNAH5* in the

IFT140 dataset is a consequence of disordered retrograde IFT, rather than disordered retrograde IFT ensuing from dynein motor assembly defects. There was also no difference between PT and *DNAH5*-GC epithelium capability to form polarised cysts from single cells. The percentage of polarised ECAD⁺ cysts was higher in both patient and gene-corrected conditions (~80%) than seen in the IFT140 dataset (40-60%). Potential explanations for this include: (i) not aspect of the disease phenotype; (ii) improved technical skill in handling the MACS sorted cells with lower cell trauma or (iii) reduced contamination of the analysis by non-epithelial or dedifferentiated cells by ECAD⁺ cyst isolation. The sampling speed from the spinning disk microscope allowed us to improve the cyst culture analysis by imaging the entire Chamberslide well for each genotype and then filtering out ECAD positive cysts and shuffling them for blinded assessment. On one hand this filtering approach standardises the comparison by isolating cysts that have arisen from a cells of a defined nephron segment, reducing the potential for differential nephron patterning to bias results. Alternatively, there is a risk that the defined segment may not express the cyst phenotype which could then be missed.

Unable to demonstrate a validating phenotype using the above methods, the variant prioritisation list was revisited to consider other potential candidates. This included differentiating a third non-isogenic iPSC clone as an external control to the *DNAH5* comparison. Disappointingly, the cyst culture from this three way experiment failed due to technical issues following mounting the slides, but given the cyst polarisation rate in the diseased lines was so high, it is unlikely the non-isogenic control would have been superior. The higher expression of genes involved in dynein motor assembly, crumbs polarity complex and cell-cell junction components demonstrated by qPCR in the diseased lines highlights the importance of isogenic controls in the field of iPSC derived organoid disease modelling. Whilst replicates of this experiment would have strengthened the data, it was exceptionally difficult to coordinate three simultaneous differentiations side by side, and unfortunately it was beyond the scope and funding of this project to repeat this.

Since the decision to model *DNAH5* c.9751G>C was made, a number of single cell RNA sequencing databases have been published illustrating low transcriptional activity of *DNAH5* in both human kidney and kidney organoids.(Wu et al., 2018a, Wu et al., 2018b,

Phipson et al., 2019) *DNAH5* is expressed at low levels in the renal epithelium single cell RNA sequencing datasets from healthy adult kidney biopsies, most prominently in the loop of Henle (~6% of cells) but also the proximal tubule and principle cells of the collecting duct (both ~4% of cells)**.(Wu et al., 2018a, Wu et al., 2018b) Our own organoid single cell RNA sequencing dataset demonstrates some *DNAH5* expression in the organoid epithelial cluster (~6% cells)(Phipson et al., 2019), though it was more poorly expressed when the Takasato organoid protocol was replicated by Wu and colleagues (~1.2%).(Wu et al., 2018b) *KDM8* is expressed at even lower levels again in human kidney (~2% of cells)(Wu et al., 2018a) and organoid (~4% of cells)(Phipson et al., 2019) epithelium. It is possible that the lower sequencing depth in single cell RNA sequencing (as compared to bulk RNA sequencing) may underrepresent the expression of these relatively lowly expressed genes. For example, *NEK8* is a well-established genotype for NPHP(Choi et al., 2013a, Grampa et al., 2016, Habbig et al., 2012, Otto et al., 2011, Otto et al., 2008) but is only expressed in <1% and 6% of the human kidney epithelial single cell RNA sequencing datasets respectively.(Wu et al., 2018a, Wu et al., 2018b) Gene expression also varies significantly in these datasets due to technical reasons with *NEK8* expression seen in up to 3% of various epithelial segments in the Wu et al replicate of the Takasato protocol(Wu et al., 2018b) but 25% of cells in the Phipson et al report of our protocol.(Phipson et al., 2019) Whilst these datasets may not be able to unequivocally advocate for gene expression in human kidney and organoid models, they represent an additional resource to contribute to the curation of future candidate variants.

Given that the *DNAH5* c.9751G>C variant was proposed on the basis of a single case, in a gene with relatively low expression in human kidney, and that ciliary length, morphology, cyst culture and focussed transcriptional signature have not revealed any significant differences, our provisional conclusion is that this variant is not disease-associated in RG1005.213.

One alternative approach to variant prioritisation is to utilise cheaper and faster preliminary *in vitro* methods to develop evidence in support of genes and variants prioritised by research genomic pipelines, before committing to organoid modelling.

Human urine derived renal epithelial cells (HURECs) are a source of primary cellular material from patients which represent a number of distinct advantages for our disease modelling program. In children, the collection of primary cells for disease modelling involves some distress, be it by skin biopsy or blood taking. Our ethical framework dictates that we cannot perform a skin biopsy or blood sample from a patient unless that procedure coincides with a clinically necessary venepuncture or anaesthetic. At present the gene editing core facility at MCRI is unable to utilise PBMC for combined reprogramming and gene correction, which is cheaper and gives rise to more clonal iPSC cell populations than a two-step process.(Howden et al., 2015, Howden et al., 2018) HURECs, however, are painless to collect, cheap to passage, tolerate freeze and thaw and maintain a high proliferation rate which is desirable for CRISPR-Cas9 gene editing. The generation of iPSC from HURECs is well documented.(Zhou et al., 2012, Zhang et al., 2015, Shi et al., 2016)

Previous reports have demonstrated the functional genomic utility of HURECs. Molinari et al characterised the tissue specific splicing of a synonymous putative splicing *NPHP3* variants in two NPHP patients with where blood and fibroblast mRNA transcript analysis was uninformative.(Molinari et al., 2018) The same group described profoundly elongated primary cilia in HURECs obtained from two siblings with compound heterozygote variants in *CEP290* and demonstrated a reduction in ciliary length when treated with Shh pathway stimulator purmorphamine and cyclin D kinase inhibitor roscovitine.(Srivastava et al., 2017b) For RG1005.213, no splicing abnormalities were identified in any of the candidate genes following whole exome sequencing of the patient HURECs. Ultimately, we had insufficient time during this candidature to optimise HUREC culture techniques, qPCR and Western blot protocols for this project. These protocols require further optimisation in our laboratory.

In summary we have been unable to validate a candidate variant for this pedigree at this time, which ultimately remains unresolved. The project has illustrated a number of learning opportunities for our program with respect to novel variant curation. A defined set of more stringent criteria, against which future candidate variants can be judged ahead of functional validation, will be necessary to optimise yield and efficiency for future projects, including but not limited to:

- i. histological phenotyping or high confidence clinical phenotyping by syndromic associations,
- ii. avoidance of genes with already established histological phenotypes,
- iii. demonstration of genotype-phenotype correlation across multiple unrelated pedigrees,
- iv. in the case of NPHP, evidence of gene product association with the primary cilia, centrosome or mitotic spindle in wild type immortalised or patient-derived cells, and/or
- v. demonstration of direct a clear truncating effect of gene or protein expression using primary cells derived from patient and related control.

Chapter 5 Kidney organoids validate *NOS1AP* as a novel, patient-derived genotype for steroid resistant nephrotic syndrome.

5.1 Introduction

The previous chapters have described iPSC derived kidney organoid modelling of NPHP, a fibrocystic kidney disease arising from the dysfunction of the renal tubular epithelium. In this chapter kidney organoids are employed to model a novel genotype associated with SRNS, an inherited glomerular disease and the second most common cause of CKD in childhood.(Fletcher et al., 2013, 2014)

5.1.1 Steroid resistant nephrotic syndrome

NS describes severe proteinuria, sufficient to lower serum protein levels to the point of decreased plasma oncotic pressure resulting in tissue oedema. In the healthy state, protein filtration across the glomerular filtration barrier is prevented by the size and charge selectivity of the slit diaphragm, a specialised protein structure bridging the foot processes of glomerular podocytes. In nephrotic syndrome, these foot processes efface and the slit

diaphragm is lost allowing large amounts of protein to cross the glomerular filtration barrier.

A proportion of patients with SRNS suffer from a genetic form of the disease. Unlike idiopathic or SSNS, genetic SRNS represent intrinsic diseases of the podocyte as evidenced by the fact that an overwhelming majority of genotypes encode proteins that are highly expressed in podocytes and essential for their structure and function.(Löwik et al., 2009, Ashraf et al., 2018, Lovric et al., 2016, Warejko et al., 2018, Machuca et al., 2009) Between 11% and 45% of SRNS patients with onset under 25 years of age show evidence for a monogenic aetiology on whole exome sequencing.(Sadowski et al., 2015, Warejko et al., 2018, Tan et al., 2018) Indeed, there are now a sufficient number of SRNS genotypes identified to cohort gene products into functional podocyte pathways including slit diaphragm associated proteins, actin binding proteins, Rho/Rac/Cdc42 regulation of actin dynamics, coenzyme Q10 biosynthesis, integrin/laminin receptor interaction and nuclear transcription factors.(Lovric et al., 2016, Preston et al., 2019)(Figure 2.5)

Clinically, genetic nephrotic syndrome is often associated with progressive, fibrotic glomerulosclerosis and an expectant decline in kidney function leading to dialysis or transplantation.(D'Agati et al., 2011) To date there are no clinically available targeted therapies for most genetic forms of NS, however potential novel therapeutic targets are emerging as the understanding of NS pathogenesis increases.(Starr et al., 2018, Zhou et al., 2017, Greenbaum et al., 2012)

5.1.2 *Kidney organoids as a model of glomerular disease.*

By transcriptional profiling, human iPSC derived kidney organoids have been demonstrated as equivalent to trimester 1-2 human fetal kidney.(Takasato et al., 2015) As such, the organoid platform is best placed to model inherited diseases with onset in infancy. Three-dimensional glomeruli isolated from iPSC-derived kidney organoids have been comprehensively transcriptionally characterised, showing that they represent superior models of human glomeruli to the previously established gold standard, conditionally immortalised 2D human podocytes.(Hale et al., 2018) In human iPSC derived from patients with congenital nephrotic syndrome due to variants in *NPHS1*, expression of the gene product nephrin and slit diaphragm development was significantly

reduced.(Hale et al., 2018, Tanigawa et al., 2018) These reports demonstrate the feasibility of iPSC derived kidney organoid glomeruli as human disease models for the validation of novel gene discoveries.

5.1.3 *Nitric oxide synthase 1 adaptor protein as a novel genotype for SRNS*

Next generation sequencing has dramatically increased the rate of gene discovery in SRNS and our understanding of the molecular basis for genetic forms of SRNS.(Vivante and Hildebrandt, 2016, Lovric et al., 2016, Sadowski et al., 2015, Tan et al., 2018, Warejko et al., 2018) A subset of SRNS associated genes have been described in mice and humans which regulate the podocyte actin cytoskeleton include Rho GTPase cell division control protein 42 (*CDC42*), RhoGTPase cofactor Rho GDP Dissociation Inhibitor Alpha (*ARHGDI1*) guanine exchange factors intersectin 1 and 2 (*ITSN1* and *ITSN2*) and neutral Wiskott-Aldrich syndrome protein (*N-WASP*).(Gee et al., 2013, Scott et al., 2012, Ashraf et al., 2018, Schell et al., 2013)

CDC42 belongs to the Rho family small GTPases, alongside *RHOA* and *RAC1*. These GTPase proteins are involved in the regulation of actin cytoskeleton dynamics, maintenance of cell adhesion, cell polarity and motility.(Etienne-Manneville and Hall, 2002, Jaffe and Hall, 2005) The maintenance of cell polarity is via the interaction of *CDC42* with the PAR polarity complex. When active *CDC42* binds to the CRIB domain of *PAR6*, it induces a conformational change in the PDZ domain which releases *aPKC* from its binding domain.(Yamanaka et al., 2001) Both *aPkc* and *Par3* have been localised to the anchor point of the slit diaphragm in immunogold EM of mouse podocyte foot processes.(Hartleben et al., 2013, Hartleben et al., 2008) Also in mice, inhibition and podocyte specific knockout of *aPkc* and *Cdc42* lead to foot process effacement and the development of nephrotic range proteinuria.(Scott et al., 2012, Choi et al., 2013b, Huang et al., 2016)

Within their database of more than 2000 genetically unresolved patients with steroid resistant nephrotic syndrome, the laboratory of Prof Hildebrandt (Boston Children's Hospital) has identified two unrelated families presenting with onset of SRNS in infancy. Proband from both families carry homozygous variants in *Nitric Oxide Synthase 1 Adaptor Protein (NOSIAP)*, a novel candidate genotype for SRNS.(Majmundar et al.

unpublished) The Hildebrandt group have demonstrated the podocyte specific expression of *NOS1AP* in both rat and human kidney in single cell RNA sequencing datasets. They have characterised HEK293 and conditionally immortalised 2D podocyte cell lines overexpressing wild type and patient-derived *NOS1AP* mutant vectors. Cells expressing *NOS1AP* mutant vectors demonstrated the reduced expression of active CDC42 levels, reduced podocyte migration and reduced podocyte expression of actin rich filopodia and podosomes. (Majmundar et al. unpublished)

In an invited collaboration with the Hildebrandt group, we set out to characterise organoids carrying homozygous, patient-derived variants in *NOS1AP*.

5.2 Methods

5.2.1 Generation of iPSC lines

A sgRNA plasmid specific to exon 5 of the *NOS1AP* locus (pSMART-sgRNA-*NOS1AP*) was generated by annealing ODNs CACCGTTACACCTGAAGATATTGC and AAACGCAATATCTTCAGGTGTAAC followed by ligation into the *BbsI* sites of the pSMART-sgRNA vector (Howden et al., 2018). To generate the *NOS1AP* template for HDR, a gblock (Integrated DNA Technologies) comprising 434 bp and 555 bp flanking the c.428G>A mutation was ligated into the pSMART-HCKan plasmid vector (Lucigen) (Figure 5.11A). A 3 bp CAG>TTC synonymous change was also included just upstream of the c.428G>A mutation to block Cas9 re-cutting and facilitate screening by allele-specific PCR. Plasmid DNA was propagated in DH5-alpha E.Coli (BIOLINE) and prepared for transfection using a Plasmid Maxi kit (QIAGEN). Transfections were performed using the Neon Transfection System (Thermo Fisher Scientific). iPSCs (derived from ATTC CRL-1502 and ATTC PCS-201010 fibroblasts) were harvested with TrypLE (Thermo Fisher) 2 days after passaging and resuspended in Buffer R at a final concentration of 1×10^7 cells/ml and added to a tube containing pSMART-sgRNA-*NOS1AP*, mRNA encoding Cas9-Gem (Howden et al., 2018, Howden et al., 2016) and the *NOS1AP* template plasmid. Electroporation was performed in a 100 μ l tip using 1100 V, 30 ms, 1 pulse. Electroporated iPSCs were plated on 6-well Matrigel-coated plates containing Essential 8 medium with 5 μ M Y-27632 (Tocris). Colonies containing the desired knock-in were screened by PCR followed by Sanger sequencing to confirm homozygosity of the c.428G>A mutation. Colonies containing successfully edited iPSCs

were subjected to a subsequent round of subcloning and screening to ensure a clonal population of gene-edited iPSCs. iPSCs were maintained and expanded at 37°C, 5% CO₂ and 5% O₂ in Essential 8 medium (Thermo Fisher Scientific) on Matrigel-coated plates with daily media changes and passaged every 3–4 days with EDTA in 1X PBS as previously described (Chen et al., 2011).

5.2.2 Differentiation of iPSC derived kidney organoids

Kidney organoids were differentiated adapting a previously reported protocol (Takasato et al., 2015) depicted in Figure 5.1C. In brief 75,000 iPSC were seeded in 6 well plates on Growth Factor Reduced Matrigel in E8 media supplemented with Revitacell (Thermo Fisher). Cells were treated with 3 days CHIR99021 (7 µM, R&D Systems, refreshed day 2) followed by 4 days FGF9 (200ng/mL) and heparin (1µg/mL) in TeSR-E6 (STEMCELL Technologies) refreshed daily. Monolayers were dissociated to a single cell suspension using TrypLE on day 7 and resuspended in 5 µL TeSR-E6 media per million cells. Cells were bioprinted as previously described (Higgins et al., 2018) The cell suspension was aspirated into a 100uL Gastight syringe with a 21-gauge Removable Needle (Hamilton) and loaded onto a NovoGen MMX bioprinter (Organovo). Eight x 4mm lines of cells were printed onto 0.4 um membrane 6 well Transwell inserts (Corning). Transwells were treated with 5 µM CHIR99021 for one hour then 5 days of FGF9/Heparin, followed by 2 days all trans retinoic acid (2µM) before withdrawal of all growth factors. TeSR-E6 was then refreshed to transwells three times weekly.

5.2.3 Cyclohexamide Treatment

Kidney organoids were treated from day 7+17 with cyclohexamide 100 µg/mL (Merck) from for 18 hours prior to RNA lysis (Bioline Isolate II). qPCR was performed according to methods outline in previous chapters.

5.2.4 Simple Western Blot

Two whole organoids were lysed in RIPA buffer with protease inhibitor (1:500) for 15 minutes on ice. Lysates were vortexed for 45 seconds and centrifuged at 13.3g for 10 minutes at 4°C. The supernatant was collected and diluted 1:5 with 1x Sample Buffer (ProteinSimple). Protein quantification was performed using a 66-440kDa plate in a

ProteinSimple Wes Capillary Western Blot analyser according to the manufacturer's instructions, modified by denaturation for 8 minutes instead of 5 minutes at 95°C.

5.2.5 *Periodic acid Schiff stain and glomerular tuft analysis.*

Organoids were fixed in 4% PFA for 6 hours. They were set in 2% agar prior to tissue processing for standard paraffin wax histology. Organoid sections were cut at 3 µm and stained with periodic acid and Schiff's reagents (PAS). Organoid glomerular tufts were defined as linear organised monolayers of podocytes lining an established extracellular matrix.

5.2.6 *Immunofluorescence*

Organoids were fixed in 2% paraformaldehyde for 20 mins on ice and washed with PBS. Whole organoids were cut from the Transwell filter and blocked/permeabilised for 3 hours in 10% Donkey serum/0.3% Triton X/PBS. Both primary and secondary antibodies were incubated overnight at 4 degrees and washed with 0.3% Triton X/PBS. DAPI and phalloidin-568 were incubated for 3 hours at room temperature. Whole mounts were cleared with 90% glycerol. Images were obtained with an Andor Dragonfly Spinning Disk confocal microscope.

5.2.7 *Quantitative immunofluorescence analysis*

Following immunofluorescent staining, three cross sectional images were obtained from each organoid using an Andor Dragonfly Spinning Disk confocal microscope using identical microscope settings. Images were blinded and shuffled. Tiff images isolating the synaptopodin channel and aPKC/PAR3 were generated and manually thresholded. These thresholds were incorporated into an automated ImageJ workflow which converted the synaptopodin threshold into a binary mask to isolate the glomerular aPKC/PAR3 signal from the non-glomerular signal. The mean fluorescence intensity ratio was calculated by dividing the glomerular MFI by the tubular MFI for each individual image.

5.2.8 *Electron microscopy*

Organoids were fixed in 2% paraformaldehyde, 2.5% glutaraldehyde in 0.1M sodium cacodylate buffer and post-fixed in 1% osmium tetroxide, 1.5% potassium ferrocyanide

in 0.1M sodium cacodylate buffer. Organoids were subsequently rinsed in distilled water then dehydrated through a graded series of alcohols before embedding in Spurr's Resin (Spurr, 1969) according to standard electron microscopy protocol. Ultrathin sections were cut with a diamond knife (Diatome, Austria) using a Leica UC7 ultramicrotome (Austria), contrasted with aqueous uranyl acetate and lead citrate before viewing in a JEOL JEM 1400Flash (Japan) transmission electron microscope at 80kV.

5.2.9 *Glomerular sieving from kidney organoids*

Glomeruli were isolated from kidney organoids using a previously published protocol (Hale et al., 2018). Twelve to sixteen whole organoids were washed with PBS and dissociated in TrypLE Select (1mL per 4 organoids per well of a 6 well plate). The dissociation was incubated at 37°C and titrated with a P1000 every three minutes until a homogenous solution was formed (roughly 15-18 minutes total). The cell-TrypLE solution was passed through 2 x 70 µm cell strainers (Falcon) and cells gently pushed through the strainer with the plunger of a 1 mL syringe before washing with 50 mL of washing buffer (5% fetal bovine serum in PBS) per strainer. The 70 µm strainers were discarded and the flow through passed sequentially through a 40 µm cell strainer (Falcon) and a 30 µm cell strainer (Miltenyi biotech), each washed with 50 mL of washing buffer. 40 µm and 30 µm were held upside down over a 92 mm petri dish and washed retrograde with washing buffer to isolate glomeruli. Isolated glomeruli were centrifuged at 2000g for 5 mins and lysed in RNA lysis buffer (Qiagen).

5.2.10 *Bulk RNA sequencing*

Bulk RNA sequencing was performed using a similar protocol to that used in Chapter 3.5.6. RNA was used to generate libraries for paired-end sequencing using an Illumina Novoseq 6000 sequencer. Reads were trimmed using Trimmomatic 0.35 (Bolger et al., 2014) and mapped to the human genome (GRCh38) with STAR aligner 2.5.3a (Dobin et al., 2013) using the quantMode feature to generate gene count matrices. Limma 3.40.6 (Ritchie et al., 2015) and EdgeR 3.26.7 (Robinson et al., 2009) were used for library normalization and differential gene expression testing. The GO function in EdgeR was used for gene ontology enrichment testing of differentially expressed gene lists.

Figure 5.1 Transcriptional evidence of *NOS1AP* in kidney organoids

(A) Single cell RNA sequencing tSNE plot illustrating *NOS1AP* expression greatest in the podocyte cell cluster identified by strong co-expression of *NPHS1*, *NPHS2* and podocalyxin. (B) Bulk RNA Expression of glomeruli isolated from WT kidney organoids demonstrates stronger expression of *NOS1AP* than 2D podocyte cultures. (C) Modified differentiation protocol.

5.2.11 Statistics

Statistical analyses of continuous variables were performed in GraphPad Prism (version 7.04) using unpaired t test with Welch's correction for unequal variance. A type I error rate of 0.05 was considered significant.

5.3 Results

5.3.1 Kidney organoid glomeruli express more *NOS1AP* than 2D podocyte cultures

As has been presented in earlier chapters, prior to functionally modelling a genotype with a kidney organoid, it is important to establish the expression pattern of that gene in the organoid. Therefore, single cell RNA sequencing datasets generated from Takasato protocol kidney organoids (Takasato et al., 2015, Phipson et al., 2017) were interrogated for *NOS1AP* expression. Consistent with the findings of the Hildebrandt laboratory in human and rat glomeruli, *NOS1AP* expression was strongest in the podocyte cluster of human kidney organoids.(Figure 5.1A) Additionally, the expression of *NOS1AP* in human organoid glomeruli was superior to 2D conditionally immortalised podocyte cultures.(Figure 5.1B)

5.3.2 Selection of *NOS1AP c.428G>A* for iPSC kidney organoid modelling

Dr Sara Howden performed combined reprogramming and *NOS1AP c.428G>A* variant insertion into CRL1502.3 (female) and ATTC PCS201010 (male) wild type cell lines. For all derived clones genotype was confirmed by Sanger sequencing. Mycoplasma screening was negative.

5.3.3 The *NOS1AP c.428G>A* allele produces a misfolded protein.

Having established *NOS1AP* was expressed in organoid glomeruli, we examined the protein localisation in the organoids by immunofluorescence. In WT organoids, whole mount immunofluorescence localised *NOS1AP* to the slit diaphragm, co-localising with synaptopodin (SYNPO) on the apical surface of podocytes and encircling a basement membrane represented by laminin- α 5 (LAMA5) immunostaining.(Figure 5.2A) Consistent with single cell RNA sequencing transcriptional data, no *NOS1AP* protein expression was detectable in proximal or distal tubular segments.(Figure 5.2B) Using the

Figure 5.2 *NOS1AP* expression in organoids

(A) WT organoid immunofluorescence demonstrating *NOS1AP* protein expression at slit diaphragm between synaptopodin (SYNPO) and laminin-A5 (LAMA5). Scale 20um. (B) Wild type organoids demonstrate isolation of *NOS1AP* expression to glomeruli (SYNPO) with no signal evident in proximal (HNF4A, nuclear) or distal (ECAD, cell wall) tubules. *NOS1AP* c.428G>A organoids demonstrated no detectable *NOS1AP* expression. Scale bar 50um. (C) Quantification of mean fluorescence intensity of *NOS1AP* in SYNPO+ glomeruli. Mean +/- SEM. Colours represent individual experiments, shapes represent genotypes (students t test, $p < 0.0001$) (D) qPCR of untreated and cyclohexamide (nonsense mediated decay inhibitor) treated whole organoids demonstrated no significant difference in *NOS1AP* expression. *MAFB* was used as a housekeeping gene to control for organoid glomerular content. (E) Simple Wes capillary western blot demonstrates no difference in *NOS1AP* protein levels in denatured lysate, once again corrected for *MAFB* expression.

same antibody in *NOS1AP*-variant organoids, no detectable *NOS1AP* immunofluorescent signal was demonstrated across both male and female iPSC background genomes and multiple differentiation experiments. (Figure 5.2B,C) In whole organoid lysates, levels of *NOS1AP* mRNA were not different when normalised to *MAFB* expression to correct for glomerular content (Figure 5.2D). Organoids treated with cyclohexamide, an inhibitor of nonsense mediated decay, showed an increase in *NOS1AP* mRNA for both lines (Figure 5.2D), suggesting the loss of immunofluorescent signal in the *NOS1AP*-variant organoid was not due to nonsense mediated mRNA decay. Similarly, *NOS1AP* protein expression measured by capillary Western blot was comparable between *NOS1AP*-variant and WT organoids (Figure 5.2E). When mapped on the protein amino acid sequence, the p.Cys143Tyr substitution created by the c.428G>A variant lies only six amino acids from the *NOS1AP* antibody immunogen (NBP2-38758). (Figure 5.3) Considered together this data suggests the absence of the *NOS1AP* immunofluorescent signal from the *NOS1AP*-variant organoid glomeruli is due to misfolding of the protein, which makes the epitope inaccessible to the *NOS1AP* antibody (Novus Biologicals - NBP2-38758).

Figure 5.3 Proximity of *NOS1AP* p.Cys143Tyr substitution to antibody epitope. Amino acid sequence of *NOS1AP* protein demonstrates the amino acid substitution is only 6 base pairs from the *NOS1AP* (NBP2-38758) antibody immunogen.

5.3.4 *NOS1AP* c.428G>A glomeruli demonstrate disordered glomerular tuft development and increased podocyte apoptosis.

Immunofluorescence analysis for slit diaphragm markers nephrin and podocin suggested a disorganisation of the *NOS1AP*-variant glomerular tissue structure. *NOS1AP*-variant glomeruli showed scattered, and in some cases punctate, nephrin/podocin co-immunofluorescence, whilst WT glomeruli demonstrated linear, organised expression of nephrin/podocin. (Figure 5.4A) This was further investigated in paraffin embedded, sectioned and periodic acid Schiff (PAS) stained organoids. *NOS1AP*-variant organoid glomeruli demonstrated abnormal glomerulogenesis, including impaired glomerular tuft

Figure 5.4 *NOS1AP*-variant organoids demonstrate abnormal glomerular development and increased podocyte apoptosis
 (A) Immunofluorescent nephrin (green) and podocin (red) staining of kidney organoids demonstrating strong, linear slit diaphragm formation in WT glomeruli and disorganised pattern in *NOS1AP*-variant organoids with small focal intensities. (scale bar 200µm larger images, 20 µm smaller images) (B) PAS Staining of WT glomeruli reveals organised tufts of podocyte monolayers lining basement membrane (BM). *NOS1AP*-variant glomeruli are disorganised and hypercellular with poorly formed BM and apoptotic figures. (scale bar 20 µm) (C-D) *NOS1AP*-variant organoids demonstrate reduced glomerular tuft length and increased pyknotic cell nuclei compared to isogenic, WT control. (students t test. mean)

Figure 5.5 Synaptopodin IHC of paraffin embedded organoid sections

formation (defined as organised monolayers of podocytes lining an area of extracellular matrix) compared to WT controls.(Figure 5.4B,C) IHC staining demonstrated apical concentration of SYNPO in WT organoids along glomerular tufts, but was more diffuse in *NOS1AP*-variant glomeruli.(Figure 5.5) *NOS1AP*-variant organoids also demonstrated an increase in pyknotic nuclei compared to control.(Figure 5.4B,D) This observation was restricted to glomeruli and did not affect tubules. This latter finding was validated by immunofluorescence for apoptosis marker caspase-3 (CASP3). *NOS1AP*-variant glomeruli demonstrated a greater mean percentage area (*NOS1AP* 18.2% vs WT 2.3%, $\Delta\mu$ 15.9%, 95%CI 12.0-19.9%, $p<0.0001$) and glomerular MFI normalised to tubular signal gated on HNF4A expression (*NOS1AP* 1.66 vs WT 0.98, $\Delta\mu$ 0.68, 95%CI 0.51-0.84, $p<0.0001$) of CASP3 expression.(Figure 5.6) This observation was once again confined to the glomerular segment.

5.3.5 *Electron microscopy of organoid glomeruli demonstrates reduction of foot process generation in NOS1AP-variant organoids.*

The fundamental podocyte morphological defect in all forms of nephrotic syndrome is the effacement of the foot processes sitting on a GBM. Given the immaturity of the GBM within a kidney organoid, previous reports have vascularised organoids by renal subcapsular transplantation in mice.(van den Berg et al., 2018, Sharmin et al., 2016, Tanigawa et al., 2018) We attempted to transplant organoids under the renal capsule of immunocompromised mice in an effort vascularise the glomeruli and demonstrate foot process effacement on a more physiological capillary basement membrane, however at explant organoids appeared to have undergone extensive stromal expansion without any residual nephron structures.(data not shown)

We therefore attempted EM of untransplanted organoids. Transmission EM of non-transplanted organoids was challenging due to the absence of any capillaries within the glomerulus. We were able to qualitatively illustrate a reduction in villous-like cellular projections between podocytes of *NOS1AP*-variant organoids compared to WT. (Figure 5.7) This was admittedly variable and may have been related to the position of the grid section within the 3D glomerulus.

Figure 5.6 Increased caspase 3 expression of *NOS1AP* c.428G>A homozygous kidney organoids (A) Immunofluorescence of whole mount organoids demonstrates increased ASP3+(red) apoptosis signal restricted to glomeruli (NPHS1, green) and absent from proximal tubule (HNF4A, magenta). Scale bar 100um. (B-D) Quantification of CASP3 signal across three paired differentiation experiments. *NOS1AP* c.428G>A homozygous organoids demonstrated increased area (B) and mean CASP3 fluorescence intensity in NPHS1+ regions with (D) and without (C) normalisation to proximal tubular (PT) signal. Error bars represent mean +/- standard error of mean.

Figure 5.7 Electron microscopy
EM of non-transplanted organoids demonstrated variably reduced presence of villous, foot process like cellular projections in *NOS1AP*-variant organoids compared to WT control (only female background iPSC clones examined).

5.3.6 *NOS1AP c.428G>A variant impairs podocyte polarity via dysfunction of the PAR polarity complex.*

The Hildebrandt laboratory had illustrated a role for NOS1AP in the promotion of active (or GTP-bound) CDC42 levels.(Majmundar et al, unpublished) Active CDC42-GTP is recognised to regulate activity of the PAR polarity complex.(Yamanaka et al., 2001). We hypothesised that the expression of PAR polarity complex proteins within *NOS1AP*-variant organoid glomeruli would be disturbed. Using blinded manual thresholding within an automated ImageJ processing macro, we illustrated reduced MFI of both aPKC (*NOS1AP* 0.46 vs WT 0.65, $\Delta\mu$ 0.19, 95%CI 0.10-0.27, $p<0.0001$) and PAR3 (*NOS1AP* 0.53 vs WT 0.70, $\Delta\mu$ 0.17, 95%CI 0.08-0.26, $p<0.0001$) in SYNPO gated glomerular regions of *NOS1AP*-variant organoids compared to WT, normalised to tubular signal.(Figure 5.8) This was consistent across multiple differentiations and both genomic backgrounds.

Because the aPKC and PAR3 analyses relied on SYNPO expression to gate for the glomerular segment, differential SYNPO expression observed on IHC (Figure 5.5) may have influenced the aPKC and PAR3 immunofluorescent readout between the two organoids. However, the SYNPO immunofluorescent signal appeared clean and thresholds were converted to a binary mask of the glomerular segment, thus we feel subtle qualitative difference in SYNPO expression on IHC is unlikely to impact on this assay. Examples of thresholding are provided in Figure 5.9.

5.3.7 *Bulk RNA sequencing of isolated organoid glomeruli is unable to illustrate NOS1AP disease specific transcriptional pathways*

Our group has previously demonstrated an ability to isolate glomeruli from kidney organoids by dissociation and sieving.(Hale et al., 2018) We hypothesised that transcriptional profiling of isolated glomeruli from the *NOS1AP*-variant and WT organoids would demonstrate dysfunctional cellular pathways specific to *NOS1AP* mediated SRNS. Glomerular isolation was performed in technical triplicate from a single paired differentiation of the two iPSC lines. Replicates clustered by genotype on principal component analysis.(Figure 5.10A) Glomerular gene expression was lower in *NOS1AP*-variant glomeruli compared to WT glomeruli and some variability was observed between

Figure 5.8 Analysis of polarity protein expression
 (A) Reduced aPKC (red) immunofluorescence in glomeruli (synaptopodin, green) of *NOS1AP*-variant organoids compared to WT. When normalised to adjacent tubular aPKC intensity, *NOS1AP*-variant glomeruli demonstrate reduced glomerular aPKC mean fluorescence intensity (3 images from each of 4 paired distinct differentiations). (B) Same for PAR3. Symbols represent paired differentiations.

Figure 5.9 Measurement of glomerular to tubular aPKC fluorescence intensity ratio. Organoids were stained with synaptopodin (SYNPO, Blue) and aPKC (Red, Scale 100 μm) and 3 images obtained by confocal microscopy (i). A blinded operator set intensity thresholds to highlight tubular aPKC (ii, red) and glomeruli (iii, SYNPO, blue) and converted these to binary masks. Subtraction of glomerular from tubular aPKC masks provided a mask that highlighted only tubular regions (iv, green). Mean intensity readouts from raw aPKC data (v) were restricted to SYNPO and Tubular masks (vi and vii). Two examples of each condition are displayed: A. *NOS1AP* c.428G>A and B. Results of glomerular:tubular aPKC and PAR3 ratio analysis are presented in Figure 5.6.

WT replicates, indicating some technical variability in the within the sieving protocol.(Figure 5.10B). Differential gene expression analysis highlighted GO terms associated with cell-cell adhesion and extracellular matrix expression.(Figure 5.10C)

Differential expression within these GO terms was largely dominated by protocadherins and ECM proteins (collagens, contactins, integrins and laminin) that we were not able to link to the proposed *NOS1AP*-variant or SRNS disease mechanisms. Furthermore, there was no evidence of an apoptotic signal consistent with the CASP3 immunofluorescence. Additionally, ion transporters were upregulated in the *NOS1AP* samples (Figure 5.10C), suggestive of the potential contamination of the glomerular lysates with tubular cells. We hypothesise that the apoptosis within *NOS1AP*-variant glomeruli rendered them more liable dissociation which may have adversely affected the efficacy of the sieving protocol, trapping tubular segments in the sieves. Consequently it is difficult to make meaningful conclusions from this bulk RNA sequencing experiment with regards to *NOS1AP* or SRNS disease pathobiology.

5.4 Discussion

The data presented in this chapter contributes to the functional genomic validation of *NOS1AP* as a novel gene associated with SRNS and extends the molecular understanding of the effect of *NOS1AP* variants on glomerular development beyond maintenance of active CDC42 levels to demonstrate disturbances in podocyte polarity.

Consistent with findings in mouse and human kidney single cell RNA sequencing datasets (Majmundar et al. unpublished), we confirm *NOS1AP* expression is isolated to the podocyte in wild-type human kidney organoids. Furthermore, we demonstrate that 3D modelling of wild-type podocytes permits increased *NOS1AP* expression compared to 2D modelling. The superior expression of podocyte genes in 3D organoid culture over 2D podocyte culture is previously established.(Hale et al., 2018) However, in this project we demonstrate that the benefits of 3D podocyte culture are not limited to improved gene expression. The organoid platform validated the spatial expression of NOS1AP protein within the human glomerulus to be slit diaphragm associated. Furthermore, organoids portrayed a segment specific tissue consequence of the *NOS1AP* patient variant in the form of aberrant glomerular development, reduced polarity expression and increased

Figure 5.10 Bulk RNA Sequencing and differential gene expression analysis of glomeruli isolated from *NOS1AP-var* and WT kidney organoids.

(A) Principle component analysis demonstrates clustering of technical replicates by genotype. (B) Expression of key glomerular genes was increased in WT compared to control but also more variable, potentially due to technical variability introduced by the sieving protocol. (C) Differential expression analysis produces ambiguous GO terms unable to be linked to *NOS1AP* gene or podocyte dysfunction.

podocyte apoptosis, representing a key advantage to organoid based disease modelling over 2D podocyte culture. The observation of no detectable signal in the *NOS1AP* c.428G>A variant organoids is most likely due to misfolding of the protein. This is consistent with *in silico* modelling of *NOS1AP*-variant protein crystal structure performed by the Hildebrandt group predicting instability of the protein and steric clashes with adjacent amino acids (Majmundar et al, unpublished) Additionally, the Hildebrandt group have been able to detect *myc*-tagged mutant vectors transfected into 2D podocytes by immunofluorescence for the *myc* epitope, indicating viability of the mutant *NOS1AP* protein within the cell. The ultimate evidence for protein misfolding will be the ability to successfully stain whole mount organoids for the mutant protein using alternative *NOS1AP* antibodies, which are in the process of being shipped from our collaborator.

The findings of aberrant glomerular development, reduced tuft length and increased podocyte apoptosis are consistent with existing literature on *aPkc* and *Cdc42* knockout models. During normal capillary loop development, podocytes extend radially inwards to encircle glomerular capillaries. In a dual knockout *aPkc α /aPkc ζ* mouse model, Hartleben et al (2013) demonstrate failure of the glomerular development at the capillary loop stage with reduced radial extension of the podocyte processes, incomplete capillary loop formation, simplified glomerular structures and proteinuria. PAS stained sections of mouse glomeruli pictured in other *aPkc* and *Cdc42* knockout mouse models illustrate similar changes and dark, condensed nuclei albeit without frank pyknosis.(Scott et al., 2012, Hirose et al., 2009) An increase in podocyte apoptosis has been demonstrated in *Cdc42* siRNA knockdown podocytes and mice treated with *Cdc42* inhibitors.(Huang et al., 2016)

Increased apoptosis is possibly more prominent in kidney organoid glomeruli due to the less physiological *in vitro* environment as well as the lack of vasculature and mesangial support for the podocytes. This may also be because the knockout of the *Cdc42/aPkc* genes in these mouse models are driven by *Nphs2* expression and therefore affect only later glomerular development. In contrast, the homozygous *NOS1AP* variant in our organoids is somatic and expressed throughout the development of the organoid. The peripheral nature of the CASP3 signal noted on immunofluorescent analysis of the *NOS1AP*-variant organoid glomeruli is reminiscent of the collapsing glomerulosclerosis

seen in *Cdc42* and *aPKC* knockout mouse models as well as the proband biopsy. *NOS1AP* is heavily expressed in the brain where it is involved in axonal projection.(Carrel et al., 2009, Carrel et al., 2015) Clinically, *NOS1AP* variants have been associated with neurodegenerative disease, stroke, mental illness, and cardiac rhythm disturbances. (Treuer and Gonzalez, 2014, Delorme et al., 2010, Freudenberg et al., 2015) *NOS1AP* is known to carry dynamic O-linked N-acetylglucosamine (O-GlcNAc) post-translational modifications on serine residues, which protect neurons from apoptosis when placed under stress by decreasing association with nNOS, modifying NF- κ B and MAPK pathways.(Zhu et al., 2015, Zou et al., 2009, Fulop et al., 2007)When the *NOS1AP* gene was mutated in rat pheochromocytoma (PC12) cells to remove serine residues known to carry O-GlcNAc residues, cell apoptosis increased.(Zhu et al., 2015) Whilst the amino acid substitution caused by the c.428G>A variant doesn't involve a serine residue, it is possible that misfolding of the mutant *NOS1AP* protein reduces O-GlcNAc modification of the protein and leaves the cell vulnerable to an uncontrolled apoptotic response to stress. Whilst further work is required to demonstrate that this phenomenon is active in podocytes, it provides a possible link between *NOS1AP* variants and the apoptosis seen in our organoid glomeruli.

We demonstrate the reduced expression of nephrin and podocin in our *NOS1AP*-variant organoid glomeruli, as well as the reduced glomerular expression of aPKC and PAR3. Immunofluorescent study of the *Cdc42* knockout mouse glomeruli demonstrated punctate immunofluorescent expression of nephrin and podocin and reduced expression of aPKC, PAR3 and ZO-1, (Scott et al., 2012) also consistent with our findings. This mouse, as well as those discussed previously, develop foot process effacement and nephrotic range proteinuria by birth, consistent with the patient phenotype.(Hirose et al., 2009, Hartleben et al., 2008, Scott et al., 2012, Huang et al., 2016, Hartleben et al., 2013) Both PAR3 and aPKC have been demonstrated to localise to the anchor point of the mouse slit diaphragm on immunogold EM.(Hartleben et al., 2008, Scott et al., 2012) The reduced linear expression of nephrin/podocin in *NOS1AP* variant organoids is also consistent with images of SYNPO and ZO-1 expression in a *PODXL*^{-/-} iPSC organoid glomerulus, another established genotype for infant onset SRNS.(Freedman et al., 2015, Kang et al., 2017, Barua et al., 2014a)

The glomerular characterisation of our *NOSIAP* *c.428G>A* homozygous organoids differs from previous organoids modelling of congenital nephrotic syndrome due to variants in *NPHS1*.(Hale et al., 2018, Tanigawa et al., 2018) Both reports utilise different protocols to model nephrin expression within patient-derived, compound heterozygous *NPHS1* variant kidney organoids.(Tanigawa et al., 2018, Hale et al., 2018) Immunofluorescent images provided in both manuscripts do not demonstrate aberrant glomerular development or podocyte apoptosis, suggesting this organoid glomerular phenotype is specific to *NOSIAP* genotype and not SRNS genes more broadly.

The success of this project validates the lessons learned from the less successful *DNAH5* variant curation and disease modelling experience. The likelihood of pathogenicity was increased by the demonstration of segregation between two unrelated families and the preliminary work performed by our collaborators. The transcriptional immaturity of the organoid model prompted the selection of the variant carried by proband (*NOSIAP* *c.428G>A*) for modelling in iPSC derived kidney organoids as this proband presented at a younger age (4 days). Additionally, in spite of a seemingly less pathogenic missense variant, this patient demonstrated more severe proteinuria and renal dysfunction thus was thought to represent a greater likelihood of establishing an *in vitro* phenotype from the immature organoid model. Finally, this proband had undergone renal biopsy, providing us with a histological confirmation of the primary phenotype and therefore an increased level of certainty in the variant.

In this project we elected to CRISPR edit the patient variant into a wild type iPSC cell line (“knock in”) rather than derive and gene edit patient iPSC. This decision was made largely on practical grounds. The derivation of patient iPSC would have required: (i) amendment to our existing HREC for recruitment of an international patient; (ii) coordination of the patient fibroblast collection (iii) expansion and transport of patient fibroblasts from a third, international collaborating centre and (iv) execution of combined reprogramming and gene correction. Collectively this process represented at best a 6-9 month delay before modelling could commence. The disadvantage of the knock-in approach includes the inability to account for any contribution of the patient’s background genome to disease phenotype. However, in this circumstance, we recapitulate our findings across two wild type iPSC backgrounds and therefore confidently confirm that this single

gene mutation is responsible for the phenotype seen in the organoids. One future advantage of the knock in approach would be to extend our research of SRNS by knocking in multiple SRNS genotypes into one reference iPSC control line, allowing all mutant clones one control, thereby minimising (i) technical variability that may otherwise arise between non-isogenic controls as well as (ii) differentiation protocol optimisation which is required for each individual line.

Our laboratory has established that organoid glomeruli are relatively more resistant to dissociation than the tubules and stroma and published protocols for their isolation.(Hale et al., 2018) The ability to generate reproducible glomerular isolation from *diseased* organoids has not been demonstrated. We propose that a lack of integrity within *NOS1AP*-variant glomeruli sufficiently confounded the ability to generate a representative glomerular lysate using this protocol. One must also consider the potential low fidelity of transcriptional profiling when studying a gene with little to no role in transcriptional regulation, such as *NOS1AP*. In other words, even if the glomerular isolates were pure, the molecular disturbance in this particular context may lack the transcriptional magnitude to be detected by bulk RNA sequencing. This argument, along with our results, also highlight the benefits of examining the whole mount organoid in preference to dissociating or disturbing the live micro-tissues.

EM of organoid glomeruli was challenging due to the lack of a capillary and glomerular basement membrane to provide a surface on which podocytes can align. Previous reports have vascularised organoids using murine subcapsular transplantation and demonstrated EM images of the glomerular filtration barrier very similar to that expected *in vivo*.(Tanigawa et al., 2018, van den Berg et al., 2018) Our attempts to replicate these protocols were unsuccessful and require optimisation. Accordingly, we analysed non-transplanted organoids and were able to appreciate a decrease in villous like cellular projections extending between *NOS1AP* variant podocytes compared to wild type, however this was variable and difficult to quantitate. Similar wild-type podocyte projections have been illustrated in previous reports and labelled as putative foot processes.(Hale et al., 2018, van den Berg et al., 2018) There are no previous reports of glomerular disease in kidney organoids examined in non-transplanted kidney organoids however 2D podocyte cultures regularly describe actin rich cell projections labelled

filopodia and podosomes as a surrogate marker of actin dynamics and podocyte function.(Welsch et al., 2001, Scott et al., 2012, Schell et al., 2013, Mattila and Lappalainen, 2008) Ultimately optimisation of murine transplantation protocols will be essential to this approach.

In conclusion, kidney organoids provided a human, *in vitro* model in which we were able to localise the spatial, 3D NOS1AP protein expression with a human glomerular slit diaphragm. Additionally, we were able to demonstrate a podocyte specific consequence of a patient specific *NOS1AP* variant including increased podocyte apoptosis and reduced glomerular tuft length, providing a link from the 2D podocyte work performed by Professor Hildebrandt's laboratory and an established murine glomerular disease phenotype in *Cdc42* conditional knockout models. At the time of writing, this is the first report of the use of kidney organoids for the validation of a novel gene for inherited kidney disease.

Figure 5.11 *NOS1AP* gene editing approach by Dr Sara Howden

(B) Sanger sequences of gDNA of WT and PT clones show knock-in of c.428G>A missense variant (red) and synonymous 3bp change (blue).

Chapter 6 Conclusions and Future Directions

This PhD commenced shortly after the first publication of iPSC-derived kidney organoid protocols.(Takasato et al., 2015, Morizane et al., 2015, Takasato et al., 2014, Freedman et al., 2015, Taguchi et al., 2014) At this time, it was unknown whether organoids differentiated from the reprogrammed iPSC of patients with inherited kidney disease would be capable of faithfully modelling disease phenotypes. This thesis sought to demonstrate the capabilities of the organoid model for the functional genomic research of glomerular and tubular disorders, first in a previously validated genotype and subsequently for novel genes associated with kidney disease.

The projects presented in this thesis, alongside those published in the field during the period of candidature (Chapter 2.6.2), demonstrate the breadth of utility of kidney organoids in the modelling of both glomerular and tubular disease. Given the developmental immaturity of the organoids, (Takasato et al., 2015) we approached diseases with onset in infancy and childhood. This rationale was based on maximising the likelihood of observing a morphological disease phenotype directly from the organoid. A

gene specific phenotype was observed in both the *IFT140* and *NOS1AP* mutant organoids. Other groups have successfully approached adult onset disease such as ADTKD-*UMOD* (Dvela-Levitt et al., 2019) and ADPKD (Cruz et al., 2017). Thus one might conclude that the sole prerequisite to studying a genetic disease in an organoid is the expression of that gene by the organoid, regardless of the age of disease onset. This may well be the case, however the absence of mature channel and transporter expression from current organoid protocols may alter the observed phenotypes seen in adult onset disease models.

One aspect of kidney organoid disease modelling that has changed little over the period of this candidature is the spectrum of diseases unable to be modelled. There exist multiple reports at vascularising organoids either using *in vitro* flow (Homan et al., 2019) or through transplantation into mice (Sharmin et al., 2016, van den Berg et al., 2018, Tanigawa et al., 2018, Subramanian et al., 2019) but despite improvements in glomerular filtration barrier formation, a model of Alport syndrome is yet to be achieved. Furthermore, very recent evidence suggests that murine subcapsular transplantation can only achieve maturation to a finite extent.(Nam et al., 2019) Protocols for the iPSC derived modelling of glomerular disease are progressing at rapid speed including ‘organ on a chip’ models.(Musah et al., 2018, Musah et al., 2017, Petrosyan et al., 2019) and protocol amendments aimed at eliminating off-target differentiated cell types.(Wu et al., 2018b)

In Chapter 3 and 4 patient-derived iPSC are used to generate organoids. However in Chapter 5, knocking the patient *NOS1AP* variant into a WT reference iPSC line was more practical. Both are reasonable approaches. The former approach requires re-optimisation of differentiation conditions for each derived iPSC clone which we have found to be cumbersome and therefore expensive. It is also more expensive if the patient iPSC reprogramming and gene correction are performed separately. The ‘knock in’ approach may reduce optimisation and cost however, in order to progress to clinically relevant personalised therapeutic screening assays, patient iPSC will eventually need to be derived and optimised. Whatever the approach, CRISPR remains an indispensable tool in generating isogenic control iPSC lines to isolate the genetic variant of interest within the experimental comparison. This is now gold standard within the field.

The multicellular nature of kidney organoids provides an *in vitro* micro-environment that more accurately reflects *in vivo* cell-cell communication and tissue function.(Pampaloni et al., 2007) The drawback of this model is the need to isolate the cell types of interest for molecular interrogation, a process not required in 2D cell cultures. This thesis illustrates methods for isolation of epithelial cells (by MACS) and glomeruli (by sieving) for bulk RNA sequencing and DGE analysis. Unsurprisingly these isolation methods are not perfect and these approaches require optimisation. For example, the differential gene expression analysis in the *IFT140* project required correction for variable nephron patterning. In future, at the expense of sequencing depth, this may be overcome by single cell RNA sequencing permitting inclusion of transcriptionally comparable cell clusters into the DGE analysis. In the *NOS1AP* project DGE did not reflect the apoptotic signals seen in whole mount staining, presumably because the apoptotic cells were washed away during the dissociation prior to glomerular isolation. Whilst these DGE analyses were able to imply dysfunctional transcriptional pathways they were not able to provide highly granular insights into molecular pathogenesis. Furthermore, dissociation is recognised to produce cellular stress responses which may pollute transcriptional analyses.(Wu et al., 2019b) Additionally, transcriptional profiling may not be an adequately sensitive modality to characterise the molecular effect of gene variants that are not transcription factors. Quantitative proteomics may be more effective in this circumstance.

Consequently, both within the projects described in this thesis and within the wider organoid disease modelling literature,(Dvela-Levitt et al., 2019, Czerniecki et al., 2018, Przepiorski et al., 2018, Hollywood et al., 2019) the greatest analytical yield has been derived from undissociated, whole mount organoid preparations. In the *IFT140* and *DNAH5* projects we performed quantitative and qualitative analysis of primary cilia morphology within a three dimensional whole mount organoid using state of the art high-resolution confocal microscopy and partially automated analysis programs. In the *NOS1AP* project we performed a fully automated, quantitative analysis of apoptosis using caspase 3 immunofluorescence. This caspase 3 assay is a candidate for a high content analysis screen of compounds which modulate CDC42 GTPase activity. However, existing attempts to culture organoids in high throughput platforms has demonstrated a high degree of variability.(Czerniecki et al., 2018) Accounting for this variability, the expense of organoid culture and sheer number of compounds in libraries available for

screening (measured in thousands), it is likely that more straightforward, 2D cell cultures will be used for primary high throughput compound screening with validation of identified candidates then tested in organoids. This elegantly illustrated by Associate Professor Anna Greka's laboratory in the characterisation of a proposed novel compound for ADTKD-*UMOD*.(Dvela-Levitt et al., 2019) Far from fantasy, the use of organoids to identify subjects that may respond to specific pharmacological treatments is already in preclinical practice. The use of primary rectal organoid assays from patients with cystic fibrosis has been shown to correlate with respiratory function test results and model respiratory response to CFTR modulation therapies.(Dekkers et al., 2016, Dekkers et al., 2013)

In Chapter 4, the unsuccessful attempt to ratify *DNAH5* as a novel genotype for NPHP highlights the importance of high quality genomic variant curation prior to the commitment to organoid modelling and the pitfall of approaching a gene for validation based on only a single affected case. Additionally, the fact that we were unable to identify any phenotypic difference between the *DNAH5* patient and gene corrected organoids within this project also speaks to the fidelity of the results in the previous *IFT140* chapter. In future, the established workflow from undiagnosed patient to organoid disease model is likely to involve greater collaboration between international clinical renal genomic databases and an element of preliminary 2D cell culture assays as an acid test, before the expense of organoid modelling can be justified.

In summary, kidney organoids represent exciting, novel, functional genomic models, clearly capable of expanding our knowledge of inherited glomerular and tubular kidney disease. Current protocols do not allow the modelling of all kidney diseases and thus organoids stand to complement existing functional genomic models, rather than replace them. The diseases best suited to modelling with kidney organoids are those where an immunofluorescent morphological readout of protein localisation, structural tissue development or function can be obtained. Isolation of specific cell types from organoids is possible but prone to technical variation which can be overcome by a sound understanding of the inherent variation in the differentiation protocol in use.

The initial hype of regenerative medicine revolved around the future prospects of culturing autologous nephron masses for use as transplantable renal replacement therapy. Kidney organoid disease modelling, however provides a far more immediately realisable clinical translation in the form of novel gene discovery, improved pathomolecular understanding, and ultimately tailored patient therapy using personalised, *in vitro* therapeutic screening. As new technologies are superimposed on existing kidney regeneration approaches, the breadth of diseases able to be modelled and thus the clinical translation of discoveries will only increase.

8.2 Appendix 2: List of Primary and Secondary Antibodies

Primary antibodies

NPHS1 (Bioscientific, AF4263, 1:300)
 biotinylated *Lotus tetragonolobus* lectin (Vector Laboratories, B-1325, 1:300)
 CDH1/ECAD (BD Biosciences, 610181, 1:300)
 CDH1/ECAD (Cell Signalling Technologies, 3195S, 1:300)
 GATA3 (R&D Systems, AF2605, 1:300)
 acetylated tubulin (Sigma Aldrich, T6793, 1:500)
 IFT140 (Proteintech, 17460-1-AP, 1:100)
 WDR19 (Proteintech, 13647-1-AP, 1:100)
 IFT88 (Proteintech, 13967-1-AP, 1:100)
 EpCAM-AF488 (Biolegend, 324210, 1:300)
 ZO1 (Life Technologies, 40-2300, 1:200)
 beta catenin (Sigma Aldrich, C2206, 1:200)
 Phalloidin-FITC (Sigma-Aldrich, P5282, 1:1000)
 PAX2 (Zymed Laboratories, 71-600, 1:300)
 LAMA5 (Abcam, AB77175, 1:300)
 HNF4A (Life Technologies, MA1-199, 1:500)
 CASP3 (Cell Signalling Technology, 9661, 1:200)
 podocin (Sigma Aldrich, P0372, 1:600)
 synaptopodin (Santa Cruz, SC21537, 1:300)
 aPKC (Santa Cruz, SC216, 1:300)
 PAR3 (Merck 07-330, 1:300, 1:300)
 NOS1AP (Novus Biologicals, NBP2-38758, 1:200)

Secondary antibodies

Streptavidin Alexa Fluor 405 conjugate (Life Technologies, S32351, 1:400)
 Alexa Fluor 488 Donkey anti-mouse IgG (H+L) (Invitrogen, A21202, 1:400)
 Alexa Fluor 488 Donkey anti-rabbit IgG (H+L) (Invitrogen, A21206, 1:400)
 Alexa Fluor 568 Donkey anti-mouse IgG (H+L) (Invitrogen, A10037, 1:400)
 Alexa Fluor 568 Donkey anti-rabbit IgG (H+L) (Invitrogen, A10042, 1:400)
 Alexa Fluor 568 Donkey anti-goat IgG (H+L) (Invitrogen, AB175704, 1:400)
 Alexa Fluor 647 Donkey anti-sheep IgG (H+L) (Invitrogen, A21448, 1:400)
 Alexa Fluor 647 Donkey anti-goat IgG (H+L) (Invitrogen, A21447, 1:400)
 Alexa Fluor 647 Donkey anti-mouse IgG (H+L) (Invitrogen, A31571, 1:400)
 Alexa Fluor 647 Donkey anti-rabbit IgG (H+L) (Invitrogen, AB150075, 1:400)
