Two Extensions of Topological Feedback Entropy

Rika Hagihara · Girish N. Nair

Abstract Topological feedback entropy (TFE) measures the intrinsic rate at which a continuous, fully observed, deterministic control system generates information for controlled set-invariance. In this paper we generalise this notion in two directions; one is to continuous, partially observed systems, and the other is to discontinuous, fully observed systems. In each case we show that the corresponding generalised TFE coincides with the smallest feedback bit rate that allows a form of controlled invariance to be achieved.

Keywords Topological entropy · communication-limited control · quantised systems

1 Introduction

In 1965, Adler, Konheim, and McAndrew [1] introduced *topological entropy* as a measure of the fastest rate at which a continuous, discrete-time, dynamical system in

a compact space generates initial-state information. Though related to the measure-theoretic notion of *Kolmogorov-Sinai entropy* (see e.g. [13]), it is a purely deterministic notion and requires only a topology on the state space, not an invariant measure. Subsequently, Bowen [3] and Dinaburg [6] proposed an alternative, metric based definition of topological entropy. This accommodates uniformly continuous dynamics on noncompact spaces and is equivalent to the original definition on compact spaces.

These concepts play an important role in dynamical systems but remained largely neglected in control theory. However, the emergence of digitally networked control systems (see e.g. [2]) over the last four decades renewed interest in the information theory of feedback, and in 2004 the techniques of Adler et al. were adapted to introduce the notion of *topological feedback entropy (TFE)* [11]. Unlike topological entropy, TFE quantifies the *slowest* rate at which a continuous, deterministic, discrete-time dynamical system *with inputs* (i.e. a control plant) generates information, with states confined in a specified compact set. Equivalently, it describes the rate at which the plant generates information relevant to the control objective of set-invariance.

From an engineering perspective, the operational significance of TFE arises from the fact that it coincides with the smallest average bit-rate between the plant and controller that allows set invariance to be achieved. In other words, if an errorless digital channel with limited bit rate R connects the plant sensor to the controller, then a coder, controller and decoder that achieve set invariance can be constructed if and almost only if R exceeds the TFE of the plant.¹ Thus set invariance is possible if and almost only if the digital channel can transport information faster than the plant generates it.

Later, the notion of *invariance entropy* was introduced for continuous, deterministic control systems in continuous time [4, 7, 8] based on the metric-space techniques of Bowen. This measures the smallest growth rate of the number of open-loop control functions needed to confine the states within an arbitrarily small distance from a given compact set. In contrast, TFE is defined in a topological space and counts the minimum rate at which initial state uncertainty sets are refined, with states confined

¹ Without loss of generality, there can also be an errorless digital channel from the controller to the plant actuator; in this case R is taken to be the minimum of the two channel rates.

to a given compact set. Despite these significant conceptual differences, it has been established that TFE and invariance entropy are essentially the same object.

A limitation of the formulations above of entropy for control systems is their restriction to plants with fully observed states and continuous dynamics. This makes them inapplicable when only a function of the state can be measured or the plant has discontinuities such as a quantised internal feedback loop. A recent article [5] studied continuous, partially observed plants in continuous time, with the objective being to keep the plant outputs arbitrarily close to a given compact set for any initial state in another set. The notion of *output invariance entropy* was defined as a lower bound on the required data rate. However, the control functions in this formulation are chosen according to the initial state. Thus when the controller has access to only the output not the state, the lower bound may be loose.

For discontinuous systems, notions of topological entropy have been proposed for piecewise continuous, piecewise monotone (PCPM) maps on an interval [10,9], using a Bowen-style metric approach. It is shown that the topological entropy of a PCPM map coincides with the exponential growth rate of the number of subintervals on which the iteration of the map is continuous and monotone. In [12], a metric approach was also adopted to define a topological entropy for a possibly discontinuous, open-loop, discrete-time system driven by a sequence of disturbances. However, it is not clear how these constructions can be adapted to feedback control systems with vector-valued states.

In this paper we use open-set techniques to extend TFE in two directions; one is to continuous plants with continuous, partial observations in section 2, and the other is to a class of discontinuous plants with full state observations in section 3. In each case we show that the extended TFE coincides with the smallest average bit-rate between the plant and controller that allows weak invariance to be achieved, thus giving these concepts operational relevance in communication-limited control.

Though both generalisations involve open covers, the assumptions and techniques underlying them are significantly different. The questions of how to compute bounds on these notions and how to construct a unified notion of feedback entropy for discontinuous, partially observed systems are ongoing areas of research.

Terminology. The nonnegative integers are denoted by \mathbb{Z}_0 and the positive integers by \mathbb{N} . Sequence segments (x_s, \dots, x_t) are denoted by x_s^t . A collection α of open sets in a topological space Z is called an *open cover* of a set $W \subseteq Z$ if $\cup_{A \in \alpha} A \supseteq W$. A subcollection $\beta \subseteq \alpha$ is called a *subcover* of W if $\cup_{B \in \beta} B \supseteq W$. If α contains at least one finite subcover of W , then $N(\alpha|W) \in \mathbb{N}$ denotes the minimal cardinality over them all; in the case where $W = Z$, the second argument will be dropped.

2 Continuous, Partially Observed Systems

In this section, we extend topological feedback entropy (TFE) to continuous, partially observed, discrete-time control systems. We then prove that the TFE coincides with the smallest average feedback bit-rate that allows a form of controlled set-invariance to be achieved via a digital channel.

2.1 Weak Topological Feedback Entropy

To improve readability, most of the proofs in this subsection are deferred to the Appendix. Let X be a compact topological space and consider the continuous, partially observed, discrete-time control system

$$\begin{aligned} x_{k+1} &= f(x_k, u_k) \in X \\ y_k &= g(x_k) \in Y \end{aligned}, \quad \forall k \in \mathbb{Z}_0, \quad (2.1)$$

where the input u_k is taken from a set U , the output y_k lies in a topological space Y , and the functions g and $f(\cdot, u)$, $u \in U$, are continuous. For simplicity write $f_u(\cdot) := f(\cdot, u)$, $f_{u_0^s} := f_{u_{s-1}} f_{u_{s-2}} \cdots f_{u_0}$ and for any $s \in \mathbb{N}$, let $g_{u_0^{s-1}}$ denote the continuous function that maps x_0 to y_0^s when the plant is fed with input sequence u_0^{s-1} . Given a compact target set $K \subsetneq X$ with nonempty interior, assume the following:

- (Ob) The plant is *uniformly controlled observable*: there exists $s \in \mathbb{Z}_0$ and an input sequence v_0^{s-1} such that the map $g_{v_0^{s-1}}$ is continuously invertible on $g_{v_0^{s-1}}(X)$.
- (WCI) The set K is *weakly controlled invariant*: there exists $t \in \mathbb{N}$ such that for any $x_0 \in X$ there exists a sequence $\{H_k(x_0)\}_{k=0}^{t-1}$ of inputs in U that ensures $x_t \in \text{int}K$.

Condition (Ob) states that there is a fixed input sequence v_0^{s-1} that allows the initial state x_0 to be recovered as a continuous function of the output sequence y_0^s . The states x_1, \dots, x_s are not required to lie inside $\text{int}K$; this gives the freedom to trade transient control performance off for improved accuracy in state estimation.

We also remark that the main difference between WCI and the usual definition of controlled set-invariance is that the state only needs to be steerable to the target set in t time steps, not one. As a technicality, the topological methods we employ also require the state x_t to lie in the interior of K .

We now introduce tools to describe the information generation rate. Pick $s \in \mathbb{Z}_0$ and an input sequence v_0^{s-1} . Let α be an open cover of $g_{v_0^{s-1}}(X) \subseteq Y^{s+1}$, τ a positive integer, and $G = \{G_k : \alpha \rightarrow U\}_{k=0}^{\tau-1}$ a sequence of τ maps that assign input values to each element of α . Define \mathcal{C} to be the set of all tuples $(s, v_0^{s-1}, \alpha, \tau, G)$ that satisfy the following constraint:

- (C) For any $A \in \alpha$ and $x_0 \in g_{v_0^{s-1}}^{-1}(A)$, the concatenated input sequence $(v_0^{s-1}, G(A))$ yields $x_{s+\tau} \in \text{int}K$, with $g_{v_0^{s-1}}$ continuously invertible on $g_{v_0^{s-1}}(X)$.

Proposition 2.1 *If (Ob) and (WCI) hold, then $\mathcal{C} \neq \emptyset$, i.e. constraint (C) is feasible.*

Next, we use α to track the orbits of the initial states. Divide time up into cycles of duration $s + \tau$ and apply an input sequence v_0^{s-1} that satisfies (Ob) for the first s instants of each cycle. Let A_0, A_1, \dots be elements of α and for each $j \in \mathbb{N}$ define

$$B_j := \left\{ x_0 \in X : \begin{array}{l} x_{i(s+\tau)} \in g_{v_0^{s-1}}^{-1}(A_i), 0 \leq i \leq j-1, \text{ and} \\ u_{i(s+\tau)}^{(i+1)(s+\tau)-1} = (v_0^{s-1}, G(A_i)), 0 \leq i \leq j-2 \end{array} \right\}. \quad (2.2)$$

In other words, B_j is the set of initial states such that during the $(i+1)$ th cycle, the sequence $y_{i(s+\tau)}^{i(s+\tau)+s}$ of the first $s+1$ outputs lies inside A_i when the sequence of $s+\tau$ inputs over the cycle is $(v_0^{s-1}, G(A_i)) \in U^{s+\tau}$ for every $i \in [0, \dots, j-2]$.

Proposition 2.2 *The set B_j has the following properties.*

- i. Each B_j is an open set.
- ii. Every $x_0 \in X$ must lie in some B_j .

Corollary 2.1 For each $j \in \mathbb{N}$ the collection of sets B_j ,

$$\beta_j := \{B_j : A_0, A_1, \dots, A_{j-1} \in \alpha\}, \quad (2.3)$$

is an open cover of X .

Now, since β_j is an open cover of X , compactness implies that it must contain a finite subcover. Consider a minimal subcover with cardinality $N(\beta_j) \in \mathbb{N}$. As no set in this minimal subcover of β_j is contained in a union of other sets, each carries new information. Thus as $N(\beta_j)$ increases, the amount of information gained about the initial state grows. In order to measure the asymptotic rate of information generation, we need the following:

Lemma 2.1 The sequence $(\log_2 N(\beta_j))_{j=1}^\infty$ is subadditive.

The next proposition follows from Fekete's lemma; see e.g. [13, Theorem 4.9] for a proof.

Proposition 2.3 The following limit exists and equals the right hand infimum:

$$\lim_{j \rightarrow \infty} \frac{\log_2 N(\beta_j)}{j(s + \tau)} = \inf_{j \in \mathbb{N}} \frac{\log_2 N(\beta_j)}{j(s + \tau)}. \quad (2.4)$$

We now define a topological feedback entropy for continuous, partially observed plants:

Definition 2.1 The *weak topological feedback entropy (WTFE)* of the plant (2.1) with target set K is defined as

$$h_w := \inf_{(s, v_0^{s-1}, \alpha, \tau, G) \in \mathcal{C}} \lim_{j \rightarrow \infty} \frac{\log_2 N(\beta_j)}{j(s + \tau)} \stackrel{(2.4)}{=} \inf_{(s, v_0^{s-1}, \alpha, \tau, G) \in \mathcal{C}, j \in \mathbb{N}} \frac{\log_2 N(\beta_j)}{j(s + \tau)}, \quad (2.5)$$

where \mathcal{C} is the set of all tuples $(s, v_0^{s-1}, \alpha, \tau, G)$ that satisfy constraint (C).

This definition reduces to the *weak invariance TFE* of [11] if the plant is fully observed, since in that case condition (Ob) is trivially satisfied with $s = 0$ and $g_{v_0^{s-1}} = g$ reducing to the identity map. Like classical topological entropy for dynamical systems [1], it measures the rate at which initial state uncertainty sets are refined as more and more observations are taken 'via' an open cover. The differences here are that

control inputs must be accommodated, only partial state observations are possible, and the slowest rate is of interest, not the fastest.

Instead of ‘pulling back’ and intersecting the open sets $A_0, A_1, \dots \in \alpha$ to form an open cover β_j of the initial state space X , suppose we simply counted the smallest cardinality of minimal subcovers of the open cover α itself, under constraint (C). It turns out that this more direct approach yields the same number:

Proposition 2.4 *The weak topological feedback entropy (2.5) for the continuous, partially observed plant (2.1) satisfies the identities*

$$\begin{aligned} h_W &= \inf_{(s, v_0^{s-1}, \alpha, \tau, G) \in \mathcal{C}} \frac{\log_2 N(\beta_1)}{s + \tau} \\ &= \inf_{(s, v_0^{s-1}, \alpha, \tau, G) \in \mathcal{C}} \frac{\log_2 N(\alpha|_{g_{v_0^{s-1}}(X)})}{s + \tau}, \end{aligned}$$

Proof Note first that by plugging $j = 1$ into the second equality in (2.5) we obtain

$$h_W = \inf_{(s, v_0^{s-1}, \alpha, \tau, G) \in \mathcal{C}, j \in \mathbb{N}} \frac{\log_2 N(\beta_j)}{j(s + \tau)} \leq \inf_{(s, v_0^{s-1}, \alpha, \tau, G) \in \mathcal{C}} \frac{\log_2 N(\beta_1)}{s + \tau}. \quad (2.6)$$

We prove that the infimum (with $j = 1$) arbitrarily close to h_W can be achieved. The definition of the WTFE, combined with the fact that $\lim_{j \rightarrow \infty} j/(j-1) = 1$ and Proposition 2.3, implies that given $\varepsilon > 0$ we can find a tuple $(s, v_0^{s-1}, \alpha, \tau, G)$ that satisfies constraint (C) and a large $j \in \mathbb{N}$ such that

$$h_W \leq \frac{\log_2 N(\beta_j)}{(j-1)(s + \tau)} = \frac{\log_2 N(\beta_j)}{j(s + \tau)} \frac{j}{j-1} \leq h_W + \varepsilon. \quad (2.7)$$

We now construct a new tuple $(s', v_0'^{s-1}, \alpha', \tau', G')$. Let s' and $v_0'^{s-1}$ be s and v_0^{s-1} chosen above. The open cover α' of $g_{v_0'^{s-1}}(X)$ in Y^{s+1} is obtained as follows. Recall that β_j is an open cover of X . We use the continuous map $g_{v_0'^{s-1}}^{-1}$ to form a collection of open sets in $g_{v_0'^{s-1}}(X)$, $\{g_{v_0'^{s-1}}(B_j) : B_j \in \beta_j\}$. Note that the union of sets $g_{v_0'^{s-1}}(B_j)$ is $g_{v_0'^{s-1}}(X)$. Since $g_{v_0'^{s-1}}(X)$ is equipped with the subspace topology of Y^{s+1} , each open set $g_{v_0'^{s-1}}(B_j)$ in $g_{v_0'^{s-1}}(X)$ can be expanded to an open set B'_j in Y^{s+1} so that $g_{v_0'^{s-1}}^{-1}$ maps points in $B'_j \cap g_{v_0'^{s-1}}(X)$ into B_j . Now $\alpha' = \{B'_j : B_j \in \beta_j\}$ is an open cover of $g_{v_0'^{s-1}}(X)$

in Y^{s+1} . Recall that each $B_j \in \beta_j$ is of the form

$$B_j = g_{v_0^{s-1}}^{-1}(A_0) \cap \Phi_{G(A_0)}^{-1} g_{v_0^{s-1}}^{-1}(A_1) \cap \Phi_{G(A_0)}^{-1} \Phi_{G(A_1)}^{-1} g_{v_0^{s-1}}^{-1}(A_2) \cap \dots \\ \dots \cap \Phi_{G(A_0)}^{-1} \dots \Phi_{G(A_{j-2})}^{-1} g_{v_0^{s-1}}^{-1}(A_{j-1}),$$

where $\Phi_{G(A)} = f_{v_0^{s-1}G(A)}$ with A_0, \dots, A_{j-1} in α . Set $\tau' = (j-1)(s+\tau) - s$ and define a sequence of τ' maps G' by $G'(B_j) = G(A_0)v_0^{s-1}G(A_1)\dots v_0^{s-1}G(A_{j-2})$. Since $(s, v_0^{s-1}, \alpha, \tau, G)$ satisfies constraint (C), by construction $(s', v_0^{s-1}, \alpha', \tau', G')$ satisfies (C). Clearly, $N(\beta'_1) = N(\beta_j)$, where $\beta'_1 = g_{v_0^{s-1}}^{-1}(\alpha')$, and from inequalities in (2.7) we have

$$h_W \leq \frac{\log_2 N(\beta'_1)}{s' + \tau'} \leq h_W + \varepsilon.$$

Since $\varepsilon > 0$ was arbitrary, the above inequalities and the earlier result in (2.6) give the first equality.

For the second equality, observe that given any tuple $(s, v_0^{s-1}, \alpha, \tau, G)$ satisfying constraint (C) we have $N(\beta_1) \equiv N(\beta_1|X) = N(\alpha|g_{v_0^{s-1}}(X))$, where $\beta_1 = g_{v_0^{s-1}}^{-1}(\alpha)$, since α is an open cover of $g_{v_0^{s-1}}(X)$ in Y^{s+1} , $g_{v_0^{s-1}}(X)$ is equipped with the subspace topology of Y^{s+1} , and $g_{v_0^{s-1}}$ is a homeomorphism from the compact space X onto $g_{v_0^{s-1}}(X)$. Thus we obtain the desired equation. \square

The first equality in this result is a technical simplification that allows the cycle index $j \in \mathbb{N}$ in the definition of WTFE to be restricted to the value 1. The second equality follows almost immediately but is conceptually more significant. In rough terms, it states that under constraint (C), the smallest growth rate of the number of ‘topologically distinguishable’ output sequences in $g_{v_0^{s-1}}(X) \subseteq Y^{s+1}$ coincides with the smallest growth rate of the number of such initial states in X .

2.2 Data-Rate-Limited Weak Invariance

The weak topological feedback entropy (WTFE) constructed in the previous subsection is defined in abstract terms. We now show its relevance to the problem of feedback control via a channel with finite bit-rate, for a general class of coding and control laws.

Suppose that the sensor that measures the outputs of the plant (2.1) transmits one discrete-valued symbol s_k per sampling interval to the controller over a digital channel. Each symbol transmitted by the coder may potentially depend on all past and present outputs and past symbols,

$$s_k = \gamma_k(\{y_i\}_{i=0}^k, \{s_i\}_{i=0}^{k-1}) \in S_k, \quad \forall k \in \mathbb{Z}_0, \quad (2.8)$$

where S_k is a coding alphabet S_k of time-varying size μ_k and $\gamma_k : Y^{k+1} \times S_0 \times \dots \times S_{k-1} \rightarrow S_k$ is the coder map at time k . Assuming that the digital channel is errorless, at time k the controller has s_0, \dots, s_k available and generates

$$u_k = \delta_k(\{s_i\}_{i=0}^k) \in U, \quad \forall k \in \mathbb{Z}_0, \quad (2.9)$$

where $\delta_k : S_0 \times \dots \times S_k \rightarrow U$ is the controller map at time k . Define the *coder-controller* as the triple $(S, \gamma, \delta) := (\{S_k\}_{k \in \mathbb{Z}_0}, \{\gamma_k\}_{k \in \mathbb{Z}_0}, \{\delta_k\}_{k \in \mathbb{Z}_0})$ of the alphabet, coder and controller sequences.

Suppose that the performance objective of the coder-controller is to render K *weakly invariant*, i.e. to ensure that there exists a time $q \in \mathbb{N}$ such that for any $x_0 \in X$, $x_q \in \text{int}K$. Let $Q_w \subseteq \mathbb{N}$ be the set of all the invariance times q of a given coder-controller that achieves this objective. For each $q \in Q_w$, a q -periodic coder-controller extension that ensures $x_q, x_{2q}, \dots \in \text{int}K$ can be constructed by ‘resetting the clock’ to zero at times $q, 2q, \dots$ ² The average transmission data rate of each q -periodic extension is simply $\frac{1}{q} \sum_{j=0}^{q-1} \log_2 \mu_j$, and the (smallest) average data rate required by the coder-controller is then

$$R := \inf_{q \in Q_w} \frac{1}{q} \sum_{j=0}^{q-1} \log_2 \mu_j \quad (\text{bits/sample}). \quad (2.10)$$

We remark that in [11], the communication requirements of the coder-controller were measured instead by the asymptotic average data rate, i.e. over all $j \in \mathbb{Z}_0$, and the weak-invariance control objective was to ensure $x_q, x_{2q}, \dots \in \text{int}K$. Thus for that coder-controller, $q\mathbb{N} \subseteq Q_w$, and applying (2.10) to it would yield a less conservative number.

The main result of this subsection follows.

² See section III in [11].

Theorem 2.1 Consider the continuous, partially observed, discrete-time plant (2.1). Suppose that the uniformly controlled observability (Ob) and weak controlled invariance (WCI) conditions hold for a given target set K .

For K to be made weakly invariant by a coder-controller of the form (2.8) and (2.9), the feedback data rate in R (2.10) cannot be less than the weak topological feedback entropy:

$$R \geq h_w.$$

Furthermore, this lower bound is tight: there exist coder-controllers that achieve weak invariance at data rates arbitrarily close to h_w .

This theorem says that weak invariance can be achieved by some coder-controller if and (almost) only if the available data rate exceeds the WTFE of the plant on the target set. This gives operational significance to WTFE and justifies its interpretation as the rate at which the plant generates information for weak-invariance.

The remainder of this subsection comprises the proof of this result.

Necessity of the Lower Bound. Let the coder-controller (S, γ, δ) achieve invariance with data rate R . By (2.10), $\forall \varepsilon > 0$ there exists $q \in \mathcal{Q}_w$ such that $x_q \in \text{int}K$ for any $x_0 \in X$ and

$$\frac{1}{q} \sum_{k=0}^{q-1} \log_2 \mu_k < R + \varepsilon. \quad (2.11)$$

Let $(S^1, \gamma^1, \delta^1)$ be the q -periodic extension, which achieves weak invariance at times $q, 2q, \dots$

We wish to transform this periodic coder-controller into another that more closely matches the structure of a WTFE quintuple and has nearly the same data rate. Specifically, we seek a periodic coder-controller each cycle of which has two phases. The first phase is an initial ‘observation’ phase, during which the controller applies a pre-agreed input sequence so as to enable the coder to determine the exact value of the current state. This is followed by an ‘action’ phase, where the current state value is used to generate symbols and controls so as to achieve weak invariance by the end of the cycle.

Let $s \in \mathbb{N}$ and the input sequence v_0^{s-1} satisfy condition (Ob). Set $\tau = q$ and construct a $(s + \tau)$ -periodic coder-controller $(S^2, \gamma^2, \delta^2)$ as follows; to simplify notation, the coding and control laws are defined only for the first cycle. First, the controller applies the input sequence $u_0^{s-1} = v_0^{s-1}$; during this time, the coder transmits an ‘empty’ symbol. For the remainder of the cycle, i.e. $s \leq k \leq s + \tau - 1$, the coder-controller implements $(S^1, \gamma^1, \delta^1)$ and obtains a new state $x_{s+\tau} \in \text{int}K$. This can be achieved by defining the coder-controller $(S^2, \gamma^2, \delta^2)$ by

$$\begin{aligned} S_k^2 &= \begin{cases} \{0\} & \text{if } 0 \leq k \leq s-1 \\ S_{k-s}^1 & \text{if } s \leq k \leq s+\tau-1 \end{cases} \\ s_k \equiv \gamma_k^2(y_0^k, s_0^{k-1}) &= \begin{cases} 0 & \text{if } 0 \leq k \leq s-1 \\ \gamma_{k-s}^1(y_s^k, s_s^{k-1}) & \text{if } s \leq k \leq s+\tau-1 \end{cases}, \\ u_k \equiv \delta_k^2(s_0^k) &= \begin{cases} v_k & \text{if } 0 \leq k \leq s-1 \\ \delta_{k-s}^1(s_s^k) & \text{if } s \leq k \leq s+\tau-1 \end{cases} \end{aligned}$$

Observe that the symbol sequence $s_s^{s+\tau-1}$ is completely determined by x_s by a fixed map that incorporates both coder and controller laws. Thus there exist maps Γ and Δ such that

$$\begin{aligned} s_s^{s+\tau-1} &\equiv \Gamma(x_s), \\ u_s^{s+\tau-1} &\equiv \Delta(s_s^{s+\tau-1}). \end{aligned} \tag{2.12}$$

Now consider the disjoint coding regions $\Gamma^{-1}(c_s^{s+\tau-1}), c_s^{s+\tau-1} \in S_s^2 \times \cdots \times S_{s+\tau-1}^2$. The total number of distinct symbol sequences is $\prod_{k=s}^{s+\tau-1} \mu_{k-s} = \prod_{k=0}^{\tau-1} \mu_k$, which must be greater than or equal to the number n of distinct coding regions. Denote these coding regions by C^1, \dots, C^n and note that $f_{v_0^{s-1}}(X) \subseteq \cup_{i=1}^n C^i$. We can now rewrite the control law in (2.12) as

$$u_s^{s+\tau-1} = \Delta^*(C^i) \quad \text{if } x_s \in C^i, \tag{2.13}$$

where $\Delta^*(C^i) = \Delta(c_s^{s+\tau-1})$ iff $C^i = \Gamma^{-1}(c_s^{s+\tau-1})$.

We now construct the open cover α of $g_{v_0^{s-1}}(X)$ and the mapping sequence $G = \{G_k : \alpha \rightarrow U\}_{k=0}^{\tau-1}$ required in the definition of the WTFE. To define α , first construct

an open cover of X as follows. Observe that for any x_s in region C^i ,

$$\Phi_{\Delta^*(C^i)}(x_s) \in \text{int}K,$$

where the left hand side denotes $f_{u_s^{s+\tau-1}}$ with the control law (2.13). By the continuity of f_u (hence of $\Phi_{\Delta^*(C^i)}$) and the openness of $\text{int}K$, it then follows that for any $x_s \in C^i$ there is an open set $O(x_s)$ that contains x_s and is such that

$$\Phi_{\Delta^*(C^i)}(x) \in \text{int}K, \quad \forall x \in O(x_s).$$

We can construct for each $i \in [1, \dots, n]$ an open set $D^i = \cup_{x_s \in C^i} O(x_s)$ so that

$$\Phi_{\Delta^*(C^i)}(x) \in \text{int}K, \quad \forall x \in D^i,$$

which is equivalent to

$$\Phi_{\Delta^*(C^i)}(D^i) \subseteq \text{int}K.$$

We then use the continuous map $h_{v_0^{s-1}} = f_{v_0^{s-1}} g_{v_0^{s-1}}^{-1}$ to form the collection $\{h_{v_0^{s-1}}^{-1}(D^i)\}_{i=1}^n$ of open sets in $g_{v_0^{s-1}}(X)$. As $g_{v_0^{s-1}}(X)$ is equipped with the subspace topology of Y^{s+1} , each open set $h_{v_0^{s-1}}^{-1}(D^i)$ in $g_{v_0^{s-1}}(X)$ can be expanded to an open set L^i in Y^{s+1} so that $h_{v_0^{s-1}}$ maps points in $L^i \cap g_{v_0^{s-1}}(X)$ into D^i . The open cover α for $g_{v_0^{s-1}}(X)$ is defined by $\alpha = \{L^1, \dots, L^n\}$. Finally, construct the mapping sequence G on α by

$$G_k(L^i) = \text{the } k\text{th element of } \Delta^*(C^i) \quad \text{for each } L^i \in \alpha \text{ and } 0 \leq k \leq \tau - 1.$$

It is evident that constraint (C) on $s, v_0^{s-1}, \alpha, \tau, G$ is satisfied.

The minimum cardinality $N(\alpha|g_{v_0^{s-1}}(X))$ of subcovers of α does not exceed the number n of sets L^i in α . From this we obtain

$$\begin{aligned} h_w &= \inf_{s, v_0^{s-1}, \alpha, \tau, G} \frac{\log_2 N(\alpha|g_{v_0^{s-1}}(X))}{s + \tau} \\ &\leq \frac{\log_2 N(\alpha|g_{v_0^{s-1}}(X))}{s + \tau} \\ &\leq \frac{\log_2 n}{s + \tau} \\ &\leq \frac{\log_2 (\prod_{k=0}^{\tau-1} \mu_k)}{s + \tau} = \frac{1}{s + \tau} \sum_{k=0}^{\tau-1} \log_2 \mu_k \leq \frac{1}{\tau} \sum_{k=0}^{\tau-1} \log_2 \mu_k. \end{aligned}$$

From (2.11) the last term of the right hand side is less than $R + \varepsilon$, since $\tau = q$. Hence $R \geq h_w$.

Achievability of the Lower Bound To prove that a data rate arbitrarily close to h_w can be achieved, we show that any tuple $(s, v_0^{s-1}, \alpha, \tau, G)$ that satisfies constraint (C) yields an $(s + \tau)$ -periodic coder-controller that renders K weakly invariant in every cycle.

Let

$$H := \frac{\log_2 N(\alpha|g_{v_0^{s-1}}(X))}{s + \tau}.$$

Recalling that α is an open cover of the compact set $g_{v_0^{s-1}}(X)$, select a minimal sub-cover of α and denote it by $\{A^1, \dots, A^m\}$, where $m = N(\alpha|g_{v_0^{s-1}}(X))$. Since $g_{v_0^{s-1}}$ is a homeomorphism from X onto $g_{v_0^{s-1}}(X)$ and $g_{v_0^{s-1}}(X)$ is equipped with the subspace topology of Y^{s+1} , we see that $\{g_{v_0^{s-1}}^{-1}(A^i)\}_{i=1}^m$ is a finite open cover of X . We construct an $(s + \tau)$ -periodic coding law using these overlapping sets as follows; to simplify notation, the coding and control laws are described only for the first cycle.

For each $k \in [0, s + \tau - 1]$, set $S_k = \{1, \dots, m\}$ if $k = s$ and $S_k = \{0\}$ otherwise.

Then let

$$s_k = \begin{cases} \min\{i : x_0 \in g_{v_0^{s-1}}^{-1}(A^i)\} & \text{if } k = s \\ 0 & \text{otherwise} \end{cases}. \quad (2.14)$$

The coding alphabet is of size $\mu_k = m$ when $k = s$ and 1 otherwise.

The next step is to construct the controller from the input sequence v_0^{s-1} and mapping sequence G . For the first s instants of the cycle, the controller applies inputs $u_0^{s-1} = v_0^{s-1}$. At time s , the coder determines the initial state $x_0 = g_{v_0^{s-1}}^{-1}(y_0^s)$. Upon receiving the symbol s_s that indexes an open set $g_{v_0^{s-1}}^{-1}(A^i)$ containing x_0 , the controller applies control inputs via the rule $u_s^{s+\tau-1} = G(A^i)$.

The coder-controller thus constructed has period $s + \tau$. By constraint (C) we have $x_{s+\tau} \in \text{int}K$, hence weak $(s + \tau)$ -invariance is achieved.

By (2.14), the average data rate over the cycle is

$$\bar{R} = \frac{\log_2 m}{s + \tau} = \frac{\log_2 N(\alpha|g_{v_0^{s-1}}(X))}{s + \tau} \equiv H.$$

As h_w is the infimum of H , for any $\varepsilon > 0$ we can find $(s, v_0^{s-1}, \alpha, \tau, G)$ yielding $H < h_w + \varepsilon$. Hence $\bar{R} < h_w + \varepsilon$. The result follows by observing that $R \leq \bar{R}$ by definition (2.10) and then choosing ε arbitrarily small.

3 Piecewise Continuous, Fully Observed Plants

In this section we introduce the notion of *robust weak topological feedback entropy* for a class of piecewise continuous, fully observed plants. We then establish the relevance of this notion for bit-rate limited control.

3.1 Robust Weak Topological Feedback Entropy

As before, let X be a compact topological space. We consider the fully observed, piecewise continuous plant

$$x_{k+1} = F(x_k, u_k) \in X, \quad \forall k \in \mathbb{Z}_0, \quad (3.1)$$

where the input u_k is taken from a set U . For simplicity write $F_u := F(\cdot, u)$ and $F_{u_0^k} := F_{u_k} \cdots F_{u_0}$. Assume that there exists a finite partition \mathcal{P} of X and that each connected component of any element of \mathcal{P} has nonempty interior. For each $u \in U$ the map F_u is continuous on each element of \mathcal{P} , i.e. F_u is piecewise continuous.

Let K be a compact target set with nonempty interior, and impose the following condition on the plant:

- (RWI) The compact set K can be made *robustly weakly controlled invariant* under F : there exists $t \in \mathbb{N}$ such that for any $x \in X$, there exists an open set $O(x)$ containing x and an input sequence $\{H_k(x)\}_{k=0}^{t-1}$ in U that ensures $x_t \in \text{int}K$ for any $x_0 \in O(x)$.

Note that this is stricter than the weak controlled invariance (WCI) condition in the previous section. It restricts our focus to plants with states that can be driven in finite time into the interior of K , despite an arbitrarily small error in the initial state measurement. This requirement is not satisfied by all discontinuous plants, but is reasonable if for instance the plant consists of an underlying continuous system with an ‘inner’ quantised control loop and an ‘outer’ control loop to be designed, i.e. $F(x, u) \equiv f(x, w, u)$, where the inner control input w is a quantised function of x . It can be shown that if f is continuous and K is WCI, then it is always possible to find a sequence of quantised *joint* inputs $(w, u) \equiv (q_1(x), q_2(x))$ that preserves WCI in the presence of small state measurement errors. Condition (RWI) then applies if the inner

loop control law is chosen to be such a robust law $q_1(x)$. For reasons of space, details are omitted.

We now introduce a feedback entropy concept for this system. The key difference from Section 2 is that the output map g is the identity and so the index s in condition (Ob) there is 0. This leads to taking an open cover α directly on X . We form a triple (α, τ, G) , where $\tau \in \mathbb{N}$ and $G = \{G_k : \alpha \rightarrow U\}_{k=0}^{\tau-1}$ is a sequence of τ maps that assign input variables to all elements of α . Let \mathcal{RC} be the set of all triples (α, τ, G) that satisfy the following constraint:

(RC) For any $A \in \alpha$ and $x_0 \in A$, the input sequence $G(A)$ yields $x_\tau \in \text{int}K$, i.e.

$$F_{G_{\tau-1}(A)} \cdots F_{G_0(A)}(A) \subseteq \text{int}K.$$

Proposition 3.1 *If condition (RWI) is assumed, then constraint (RC) is feasible, i.e. $\mathcal{RC} \neq \emptyset$.*

Proof We give a complete proof to emphasise the difference from the setting in Section 2, cf. Proposition 2.1. Assume (RWI). We construct (α, τ, G) that satisfies (RC) as follows. Set τ equal to t in (RWI). By (RWI), for each $x \in X$ there is an open set $O(x)$ that contains x and is such that $F_{H_{\tau-1}(x)} \cdots F_{H_0(x)}(O(x)) \subseteq \text{int}K$. By ranging x in X we form an open cover of X , $\{O(x) : x \in X\}$. The compactness of X implies that there exists a finite subcover $\alpha = \{O(x_q)\}_{q=1}^r$. Construct the sequence $G = \{G_k\}_{k=0}^{\tau-1}$ of τ maps on α by

$$G_k(O(x_q)) = H_k(x_q) \quad \text{for each } 1 \leq q \leq r \text{ and } 0 \leq k \leq \tau - 1.$$

By construction we have that if $x \in O(x_q)$ for some $1 \leq q \leq r$ then

$$F_{G(O(x_q))}(x) = F_{\{H_k(x_q)\}_{k=0}^{\tau-1}}(x) \in \text{int}K.$$

This confirms the feasibility of (RC) under (RWI). □

Motivated by Proposition 2.4, we introduce the following concept:

Definition 3.1 The *robust weak topological feedback entropy (RWTFE)* of the plant (3.1) is

$$h_{\text{rw}} := \inf_{(\alpha, \tau, G) \in \mathcal{RC}} \frac{\log_2 N(\alpha)}{\tau}. \quad (3.2)$$

Unlike TFE and the classical topological entropy, this definition does not involve pulling back and intersecting the sets in α to measure the rate at which initial state uncertainty sets are refined. Thus it cannot be viewed *a priori* as an index of the rate at which the plant generates initial-state information. However, such an interpretation becomes plausible due to the results in the next subsection.

3.2 Robust Weak Invariance Under a Data-Rate Constraint

We now show the relevance of robust weak topological entropy to the problem of feedback control via a channel with finite bit-rate.

Consider the fully observed, piecewise continuous plant (3.1). We now introduce a feedback loop with a coder-controller of the general form (2.8)–(2.9), but with the outputs y_i replaced by states x_i . The performance objective of the coder-controller is to render K *robustly weakly invariant*, that is, to guarantee that $\exists q \in \mathbb{N}$ such that $\forall x_0 \in X$, there is an open neighbourhood $O(x_0) \ni x_0$ with the property that the input sequence u_0^{q-1} generated by the coder-controller (S, γ, δ) acting on x_0 ensures $F_{u_0^{q-1}}(x) \in \text{int}K$, $\forall x \in O(x_0)$. In other words, we desire that the control inputs generated by (2.8)–(2.9) for a plant with nominal initial state x_0 should still succeed in achieving weak q -invariance if the true initial state x is sufficiently close.

Let $Q_{\text{rw}} \subseteq \mathbb{N}$ be the set of all the robust weak invariance times q of a given coder-controller that achieves this objective. For each $q \in Q_{\text{rw}}$, we can construct a q -periodic coder-controller extension by ‘resetting the clock’ to zero at times $q, 2q, \dots$ ³ As before, the (smallest) average data rate required by the coder-controller is then

$$R := \inf_{q \in Q_{\text{rw}}} \frac{1}{q} \sum_{j=0}^{q-1} \log_2 \mu_j. \quad (3.3)$$

The main result of this subsection follows:

Theorem 3.1 *Consider the piecewise continuous, fully observed plant (3.1) with a compact target set K having nonempty interior. Assume that initial states are in the compact topological space X . Suppose that the robust weak invariance condition (RWI) holds on F, K, U .*

³ See section III in [11].

For K to be made robustly weakly invariant by a coder-controller of the form (2.8)–(2.9), the feedback data rate R in (3.3) cannot be less than the robust weak topological feedback entropy (3.2):

$$R \geq h_{\text{rw}}.$$

Furthermore, this lower bound is tight: there exist coder-controllers that achieve robust weak invariance at data rates arbitrarily close to h_{rw} .

The rest of this subsection consists of the proof of this result.

Necessity of the Lower Bound. Pick an arbitrarily small $\varepsilon > 0$. Given a coder-controller (S, γ, δ) that achieves robust weak invariance, there exists a robust weak invariance time $q \in \mathbb{N}$ such that

$$\frac{1}{q} \sum_{k=0}^{q-1} \log_2 \mu_k \leq R + \varepsilon.$$

Set $\tau = q$ and note that the symbol sequence $s_0^{\tau-1}$ is completely determined by the initial state x_0 , i.e. there exist maps Γ and Δ such that

$$\begin{aligned} s_0^{\tau-1} &\equiv \Gamma(x_0) \\ u_0^{\tau-1} &\equiv \Delta(s_0^{\tau-1}). \end{aligned} \tag{3.4}$$

Now consider the disjoint regions $\Gamma^{-1}(c_0^{\tau-1}) \subseteq X$ as the symbol sequence $c_0^{\tau-1}$ varies over all possible sequences in $S_0 \times \cdots \times S_{\tau-1}$. The total number of distinct symbol sequences is $\prod_{k=0}^{\tau-1} \mu_k$, and hence the total number n of distinct coding regions does not exceed it. Denote these coding regions by C^1, \dots, C^n and note that $X = \cup_{i=1}^n C^i$. We can then rewrite the control equation in (3.4) as

$$u_0^{\tau-1} = \Delta^*(C^i) \quad \text{if } x_0 \in C^i \tag{3.5}$$

by defining the map $\Delta^*(C^i) = \Delta(c_0^{\tau-1})$ iff $C^i = \Gamma^{-1}(c_0^{\tau-1})$.

We now construct the open cover α and the mapping sequence $G = \{G_k : \alpha \rightarrow U\}_{k=0}^{\tau-1}$ required in the definition of RWTFE. Before we define α , observe that for any x in coding region C^i ,

$$\Phi_{\Delta^*(C^i)}(x) \in \text{int}K,$$

where the left hand side denotes the dynamical map $F_{u_0^{\tau-1}}$ applied with the input sequence (3.5). By robust weak invariance, it then follows that for any $x \in C^i$ there is an open set $O(x)$ that contains x and is such that

$$\Phi_{\Delta^*(C^i)}(x_0) \in \text{int}K \quad \text{for any } x_0 \in O(x).$$

We can construct for each $1 \leq i \leq n$ an open set $L^i = \cup_{x \in C^i} O(x)$ so that

$$\Phi_{\Delta^*(C^i)}(x_0) \in \text{int}K \quad \text{for any } x_0 \in L^i,$$

which is equivalent to

$$\Phi_{\Delta^*(C^i)}(L^i) \subseteq \text{int}K.$$

As $C^i \subseteq L^i$ and $X = \cup_{i=1}^n C^i$, we have an open cover $\alpha = \{L^1, \dots, L^n\}$ for X . Finally, construct the mapping sequence G on α by

$$G_k(L^i) = \text{the } k\text{th element of } \Delta^*(C^i) \quad \text{for each } L^i \in \alpha \text{ and } 0 \leq k \leq \tau - 1.$$

It is evident that constraint (RC) on (α, τ, G) is satisfied.

By construction we know that $N(\alpha) \leq n$ and we obtain

$$\begin{aligned} h_{\text{rw}} &:= \inf_{(\alpha, \tau, G) \in \mathcal{R}\mathcal{C}} \frac{\log_2 N(\alpha)}{\tau} \\ &\leq \frac{\log_2 N(\alpha)}{\tau} \\ &\leq \frac{\log_2 n}{\tau} \\ &\leq \frac{\log_2 \left(\prod_{k=0}^{\tau-1} \mu_k \right)}{\tau} = \frac{1}{\tau} \sum_{k=0}^{\tau-1} \log_2 \mu_k \leq R + \varepsilon. \end{aligned}$$

Since ε was arbitrary, we have the desired result.

Achievability of the Lower Bound. To prove that data rate arbitrarily close to h_{rw} can be achieved, we first show that any triple (α, τ, G) that satisfies constraint (RC) with K induces a coder-controller that renders K robustly weakly invariant. Given such a triple, define

$$H := \frac{\log_2 N(\alpha)}{\tau}.$$

Recalling that α is an open cover of compact set X , select and denote by $\{D^1, \dots, D^m\}$ a minimal subcover of α , where $m = N(\alpha)$.

We construct a τ -periodic coding law using these overlapping sets via the rule

$$s_k = \begin{cases} \min\{i : x_0 \in D^i\} & \text{if } k = 0 \\ 0 & \text{otherwise} \end{cases}, \quad 0 \leq k \leq \tau - 1.$$

The coding alphabet is of size $\mu_k = m$ when $k = 0$ and 1 otherwise.

The next step is to construct the controller from the mapping sequence G . Upon receiving the symbol $s_0 = i$ that indexes an open set D^i in the minimal subcover of α , containing x_0 , the controller applies the input sequence

$$u_0^{\tau-1} = G(D^i)$$

By assumption (α, τ, G) satisfies constraint (RC). From this it is easy to see that K is robustly weakly invariant with the coder-controller and τ defined above.

By (3.2), the average data rate over the cycle is

$$\bar{R} = \frac{\log_2 m}{\tau} = \frac{\log_2 N(\alpha)}{\tau} \equiv H.$$

As h_{rw} is the infimum of H , for any $\varepsilon > 0$ we can find (α, τ, G) yielding $H < h_{\text{rw}} + \varepsilon$. Hence $\bar{R} < h_{\text{rw}} + \varepsilon$. The result follows by observing that $R \leq \bar{R}$ by definition (3.3) and then choosing ε arbitrarily small.

4 Conclusion

In this paper we used open set techniques to propose two extensions of topological feedback entropy (TFE) ; one is to continuous plants with continuous, partial observations, and the other to a class of discontinuous plants with full state observations. In each case we showed that the extended TFE coincides with the smallest average bit-rate between the plant and controller that allows weak invariance to be achieved, thus giving these concepts operational meaning in communication-limited control.

Our focus here has been on formulating the concepts of TFE rigorously and showing the fundamental limitations they impose on the communication rates needed for control. Future work will focus on computing upper and lower bounds on them for various system classes, and on strengthening the weak-invariance objective to controlled invariance.

Another important question left for future work is: how to construct a unified notion of TFE for discontinuous, partially observed plants. Such a notion would be an important step toward a theory of information flows for cooperative nonlinear control systems interconnected by digital communication channels.

A Proof for Proposition 2.1

Assume (Ob) and (WCI). Suppose that s and v_0^{s-1} satisfy (Ob). We construct α, τ, G that satisfy (C) as follows. Set τ equal to t in (WCI). For α , we first observe the following. By (WCI), the continuity of f_u , and openness of $\text{int}K$, for any $x_s \in X$ there is an open set $O(x_s)$ in X that contains x_s and is such that $f_{H_{\tau-1}(x_s)} \cdots f_{H_0(x_s)}(O(x_s)) \subset \text{int}K$. By ranging x_s in $f_{v_0^{s-1}}(X)$ we obtain an open cover $\{O(x_s) : x_s \in f_{v_0^{s-1}}(X)\}$ of $f_{v_0^{s-1}}(X)$ in X .

We then use the continuous map $h_{v_0^{s-1}} := f_{v_0^{s-1}} g_{v_0^{s-1}}^{-1}$ to form the collection of open sets in $g_{v_0^{s-1}}(X)$, $\{h_{v_0^{s-1}}^{-1}(O(x_s)) : x_s \in f_{v_0^{s-1}}(X)\}$. Note that the union of sets $h_{v_0^{s-1}}^{-1}(O(x_s))$ is $g_{v_0^{s-1}}(X)$. Since $g_{v_0^{s-1}}(X)$ is equipped with the subspace topology of Y^{s+1} , each open set $h_{v_0^{s-1}}^{-1}(O(x_s))$ in $g_{v_0^{s-1}}(X)$ can be expanded to an open set $S'(x_s)$ in Y^{s+1} so that $h_{v_0^{s-1}}$ maps points in $S'(x_s) \cap g_{v_0^{s-1}}(X)$ into $O(x_s)$. Now $\{S'(x_s) : x_s \in f_{v_0^{s-1}}(X)\}$ is an open cover of $g_{v_0^{s-1}}(X)$ in Y^{s+1} .

The open cover α of $g_{v_0^{s-1}}(X)$ in Y^{s+1} is then chosen to be a finite subcover $\{L^1, \dots, L^r\}$ of $\{S'(x_s)\}$. The existence of a finite subcover is guaranteed by the compactness of $g_{v_0^{s-1}}(X)$ as the image of the compact set X under the continuous map $g_{v_0^{s-1}}$. Let x_s^q be the point in $f_{v_0^{s-1}}(X)$ such that $L^q = S'(x_s^q)$, and let

$$G_k(L^q) = H_k(x_s^q), \quad 1 \leq q \leq r, 0 \leq k \leq \tau - 1.$$

By construction we have that if $x_0 \in g_{v_0^{s-1}}^{-1}(L^q)$ then

$$f_{v_0^{s-1}G(L^q)}(x_0) = f_{v_0^{s-1}}\{H_k(x_s^q)\}_{k=0}^{\tau-1}(x_0) \in \text{int}K.$$

This confirms the feasibility of (C) under (Ob) and (WCI).

B Proof for Proposition 2.2

The openness of B_j is confirmed by writing it as

$$B_j = g_{v_0^{s-1}}^{-1}(A_0) \cap \Phi_{G(A_0)}^{-1} g_{v_0^{s-1}}^{-1}(A_1) \cap \Phi_{G(A_0)}^{-1} \Phi_{G(A_1)}^{-1} g_{v_0^{s-1}}^{-1}(A_2) \cap \cdots \\ \cdots \cap \Phi_{G(A_0)}^{-1} \cdots \Phi_{G(A_{j-2})}^{-1} g_{v_0^{s-1}}^{-1}(A_{j-1}),$$

where $\Phi_{G(A)} := f_{v_0^{s-1}G(A)}$ is a continuous map.

Since $g_{v_0^{s-1}}$ is continuous and α is an open cover of $g_{v_0^{s-1}}(X)$ in Y^{s+1} , the collection $\{g_{v_0^{s-1}}^{-1}(A) : A \in \alpha\}$ is an open cover of X . Hence any $x_0 \in X$ must be in some $g_{v_0^{s-1}}^{-1}(A_0)$, $A_0 \in \alpha$. Then constraint (C) implies

that the $s + \tau$ inputs $v_0^{s-1}G(A_0)$ forces $x_{s+\tau} \in \text{int}K \subset X$. Repeating this process indefinitely, we see that for any $x_0 \in X$ there is a sequence A_0, A_1, \dots of sets in α such that $x_{i(s+\tau)} \in g_{v_0^{s-1}}^{-1}(A_i)$ when the input sequences $u_{i(s+\tau)}^{(i+1)(s+\tau)-1}$ are used.

C Proof for Lemma 2.1

For each $j, k \in \mathbb{N}$, the collection β_{j+k} consists of all sets of the form

$$B_{j+k} = \left[g_{v_0^{s-1}}^{-1}(A_0) \cap \Phi_{G(A_0)}^{-1} g_{v_0^{s-1}}^{-1}(A_1) \cap \dots \cap \Phi_{G(A_0)}^{-1} \dots \Phi_{G(A_{j-2})}^{-1} g_{v_0^{s-1}}^{-1}(A_{j-1}) \right] \\ \cap \Phi_{G(A_0)}^{-1} \dots \Phi_{G(A_{j-1})}^{-1} \left(g_{v_0^{s-1}}^{-1}(A_j) \cap \Phi_{G(A_j)}^{-1} g_{v_0^{s-1}}^{-1}(A_{j+1}) \cap \dots \right. \\ \left. \dots \cap \Phi_{G(A_j)}^{-1} \dots \Phi_{G(A_{j+k-2})}^{-1} g_{v_0^{s-1}}^{-1}(A_{j+k-1}) \right),$$

where $\Phi_{G(A)} = f_{v_0^{s-1}G(A)}$ with A_0, \dots, A_{j+k-1} ranging over α . Note that the expression inside the square brackets runs over all sets in β_j , while the expression inside the large parentheses runs over all sets in β_k . Constrain $\{A_i\}_{i=0}^{j-1}$ to index sets in a minimal subcover β'_j of β_j , and $\{A_i\}_{i=j}^{j+k-1}$ to those in a minimal subcover β'_k of β_k . Denote the constrained family of sets B_{j+k} thus formed by β_{j+k}^* .

We claim that β_{j+k}^* is still an open cover for X . To see this, observe that any $x_0 \in X$ must lie in a set $B'_j \in \beta'_j$ indexed by some sequence $\{A_i\}_{i=0}^{j-1}$ in α . Furthermore, $\Phi_{G(A_{j-1})} \dots \Phi_{G(A_0)}(x_0) \in \text{int}K \subset X$ and thus lies in some set B'_k in the minimal subcover β'_k . Hence $x_0 \in \Phi_{G(A_0)}^{-1} \dots \Phi_{G(A_{j-1})}^{-1}(B'_k)$ and so β_{j+k}^* is still a cover for X . As there are $N(\beta_j)$ sets in β'_j , and to each there correspond $N(\beta_k)$ possible sets in β'_k , the number of distinct elements in β_{j+k}^* is less than or equal to $N(\beta_j)N(\beta_k)$. By the definition of minimal subcovers we have that for any $j, k \in \mathbb{N}$,

$$N(\beta_{j+k}) \leq N(\beta_j)N(\beta_k).$$

Take logarithm with base 2 on each side of the inequality.
