1 **Abstract**

2 INTRODUCTION: Due to size and close proximity to skin, the sternum is a
3 complicated target for stereotactic ablative body radiotherapy (SABR). This is a
4 retrospective case series of single fraction SABR to sternal metastasis in
5 patients with oligometastatic breast cancer.

6
7 METHODS: Between June 2014 and June 2018, ten breast cancer patients
8 received 20Gy in 1 fraction to a solitary sternal metastasis. Eligible patients had
9 Eastern Cooperative Oncology Group performance status of 0-2,
10 oligometastatic disease (defined as 1-5 metastases) and a controlled primary
11 site. Patients were treated with 3-dimensional conformal radiotherapy, each
12 patient case comprising of >6 co-planar beams and 2-6 non-coplanar beams.
13 Local control, pain response and adverse events were retrospectively reviewed.

14
15 RESULTS: The median planned target volumes was 84.75cc (range, 14.4–
16 197.8cc). The median conformity index was 1.29 (range, 1.2-1.49). At a median
17 follow-up of 32 months, nine patients achieved in-field control. Two patients had
18 triple negative disease, one of them developed marginal recurrence, and the
19 other had in-field recurrence. Seven patients had sternal pain prior to SABR,
20 and within 3 months after SABR treatment the pain improved (n=3) or resolved
21 (n=2). Four patients developed acute grade 1 and 2 skin reactions, and two
22 patients had late grade 1 skin reactions. There were no grade 3 or 4 toxicities.

23
24 CONCLUSION: Our case series demonstrates safety of SABR with associated
25 disease control and analgesic benefit in selected patients with oligometastatic
26 breast cancer. The marginal recurrence observed in this cohort suggests wider
27 margins could be beneficial to account for microscopic disease.

32 Introduction

33 Bone is the most frequent site of breast cancer metastasis with bone only
34 metastases occurring in approximately 50% of patients with bone relapse[1].
35 Patients with bone only metastatic disease have a longer survival than patients
36 with visceral metastases – up to 20% alive at 5 years[2], with a median survival
37 of over 72 months in selected patients[3, 4]. Kozumi et al. found, the sternum
38 was the most common metastatic site – occurring in 34% of patients with
39 solitary bone metastases[5]. Furthermore, solitary sternal metastases remained
40 solitary for longer than patients with solitary lesions at other sites. Additionally, a
41 multivariate analysis suggests that solitary skeletal metastasis is a favourable
42 independent prognostic factor to multiple skeletal metastases. It has been
43 hypothesised that solitary sternal metastases may have a superior prognosis as
44 they may be caused by local invasion from either the primary site or adjacent
45 lymph nodes rather than via lymphatic or haematogenous channels[6].

46
47 Based on this hypothesis, previous attempts at achieving local control have
48 included resection of isolated sternal metastases. Surgical management
49 remains controversial with limited literature consisting of retrospective case
50 reports and case series. Two case series have shown surgical resection is
51 feasible, and could be curative in carefully selected patients[7, 8]. There were
52 good long term local control, pain relief and improved cosmesis[7]. An
53 aggressive treatment approach to solitary sternal metastases may provide a
54 cure in patients with metastatic breast cancer[9]. Christopherson et al. suggest
55 that curative intent treatment with chemotherapy, surgery and radiation for
56 patients with breast cancer metastatic to the sternum and/or mediastinum has
57 comparable outcomes similar to those of stage IIIC disease[10]. However,
58 issues with the potential morbidity of surgical extirpation has tempered
59 enthusiasm of this approach.

60
61 Stereotactic ablative body radiotherapy (SABR) has now emerged as a non-
62 invasive technique to treat oligometastatic disease, utilising large doses of
63 radiation in a highly conformal manner. A growing body of literature has

64 reported on the use of SABR for oligometastatic disease[11]. In particular, our
65 institution has significant experience in utilising single fraction SABR for the
66 treatment of oligometastases[12].

67

68 To our knowledge there are no reports describing SABR being used to treat
69 sternal metastases in oligometastatic breast cancer. In this report we present
70 our institutional experience with SABR to sternal metastases using a single-
71 fraction approach in patients with oligometastatic breast cancer.

72

73 **Methods and materials**

74 Following approval by our ethics committee, we reviewed all patients with
75 breast cancer who underwent SABR to a sternal metastasis between June
76 2014 and June 2018. All patients met the following criteria for receiving SABR;
77 ECOG performance 0-2, oligometastatic disease (1-5 metastases) and a
78 controlled primary site.

79

80 All patients underwent computer tomography (CT)-based planning. Patients
81 were immobilised with a personalised foam cradle, a commercial vacuum
82 immobilization device (BodyFix, Stockholm, Sweden), or a 5-points head, neck
83 and shoulders immobilisation mask (Efficast, Antwerp, Belgium). A free
84 breathing three-dimensional CT planning scan (3DCT) or a four-dimensional CT
85 planning scan (4DCT) with 3mm slice spacing was obtained for each patient
86 (Philips Brilliance Widebore). The 4DCT scans were obtained under free
87 breathing and with respiratory monitoring (RPM ,Varian Medical Systems, Palo
88 Alto CA). An average CT and maximum intensity projection (MIP) CT were
89 reconstructed. All planning CT scans were then fused with PET scan, and were
90 fused with MRI if available.

91

92 The gross tumour volume (GTV) included the tumour seen on all available
93 imaging. For patients who had a 4DCT planning scan, an internal target volume
94 (ITV) combined volumes of GTV at various phases of respiration. There was no
95 clinical target volume (CTV) delineated in patients treated between 2014 and

96 2016. The two patients treated in 2017 and 2018 had a margin of 5mm given to
97 the GTV to define a CTV. A margin of 5 mm was given to the GTV, ITV or CTV
98 to define a planning target volume (PTV).

99

100 Patients were treated with 3-dimensional conformal radiotherapy (3DCRT).
101 Beam arrangement was customised and selected based on clinical experience,
102 each patient case comprising of at least 7 co-planar beams and 2-6 non-
103 coplanar beams (

104 Figure 1). 3DCRT was used because it was quick to plan and deliver, allowed
105 easy incorporation of non-coplanar beams, achieved good PTV coverage and
106 met organs at risk (OAR) dose constraints.

107

108 A single fraction of 20Gy was prescribed to the isodose line covering $\geq 99\%$ of
109 the PTV. The dose constraints for the organs at risk were informed by
110 QUANTEC recommendation guidelines, completed RTOG protocols, and the
111 AAPMTG101 working party consensus guidelines[13, 14]. The dose constraint
112 for the spinal canal was $0.03\text{cc} \leq 12\text{Gy}$, skin was $0.03\text{cc} \leq 24\text{Gy}$, combined
113 lungs was $1000\text{cc} \leq 7.4\text{Gy}$, oesophagus was $0.03\text{cc} \leq 15.4\text{Gy}$ and heart was
114 $15\text{cc} \leq 16\text{Gy}$. All the target volumes were located close to the skin surface, and
115 most were long and cylindrically shaped. As a result, the skin dose constraint
116 was the most difficult to achieve.

117

118 Varian Eclipse computer software (Version 11 and 13 with AAA dose calculation
119 algorithm) was used to develop the treatment plans. The treatments were
120 delivered by Varian linear accelerators (21 series and TrueBeam with 5mm
121 MLC width) using 6MV photons. A kilovoltage cone beam CT scan was
122 acquired for localisation prior to treatment delivery, and repeated mid-treatment.

123

124 Patients received concurrent and/or adjuvant endocrine, targeted or immune
125 therapy as per the treating oncologist. No patient received concurrent or
126 adjuvant cytotoxic chemotherapy within three weeks of the SABR fraction.

127

128 All patients were assessed one month after treatment for acute side effects and
129 pain response. They were then reviewed every three months up to 24 months
130 to assess for events using NCI CTCAE V4.0. A routine FDG PET scan within 12
131 months after SABR was used for response assessment. Local control defined
132 as the absence of progression at the treatment site per PERCIST 1.0
133 criteria[15]. In-field recurrence was defined as any recurrence occurred within
134 the isodose line corresponding to the prescription dose and marginal recurrence
135 as any recurrence occurred between the prescription isodose line and the line
136 corresponding to the 50% of the prescription dose. Additional CT scans were
137 typically organised every three to six months by the treating oncologist. Treated
138 sternal metastasis control at the time of last follow-up was determined by the
139 patient's most recent radiological investigations using MDA classification of
140 bone response[16] and/or PET scan. The radiological investigations completed
141 after SABR were also used to determine the time to distant relapse. Distant
142 relapse was defined as any recurrence occurred outside of the line
143 corresponding to the 50% of the prescription dose.

144

145 Descriptive statistics were used to analyse the collected data.

146

147 **Results**

148 A total of ten breast cancer patients with solitary sternal metastasis treated with
149 SABR were identified and included in this case series. The baseline
150 demographic and clinical data of these patients are detailed in Table 1. The
151 median patient age was 56 years old and the median gross tumour volume was
152 26.65cc (range, 3.0cc - 103.4cc). The mean duration from the time of initial
153 breast cancer diagnosis to the development of sternal metastasis was six years.
154 Six of the ten patients had solitary sternal metastases. Eight patients had
155 previous radiotherapy to the breast or chest wall. None of the patients had
156 concurrent chemotherapy or immunotherapy during SABR.

157

158 The treatment plan details for each patient are detailed in Table 2. The median
159 planned target volume was 84.75cc (range, 14.4 – 197.8cc), and the median

160 length was 6.1cm (range, 3.5 - 12.2). The median conformity index was 1.29
161 (range, 1.2 - 1.49). The maximum skin dose ranged from 8.6Gy to 24.5Gy.

162

163 *Median follow-up duration after SABR was 32 months (range, 11 – 55 months) (Table 3). The PET*
164 *restaging scan within 12 months after SABR showed that six patients achieved complete metabolic*
165 *response within the PTV, two patients had stable metabolic disease and one patient had partial metabolic*
166 *response. One of the ten patients had the post treatment PET scan at 18 months after SABR instead of 12*
167 *months. The PET scan for this patient showed complete metabolic response of the treated site. At 13*
168 *months, one of these patients had in-field recurrences superiorly and inferiorly (*

169 *Figure 2).* Another patient at 2 months developed a marginal recurrence inferior
170 to the PTV. Both of these patients had triple negative breast cancer. At last
171 follow-up, nine patients achieved in-field control of their treated sternal
172 metastasis. Seven patients had distant relapse after SABR and the median time
173 to distant relapse was 11 months (range, 2 - 20 months). At the time of analysis,
174 one patient had died two weeks after their last follow-up.

175

176 Seven patients had pain from their sternal metastasis prior to treatment (Table
177 3). Two of these patients were pain-free within three months after their SABR
178 treatment. Three patients had an improvement in their pain after SABR
179 treatment. One of these patients had a pathological fracture of the sternum prior
180 to SABR and the pain improved within three months after SABR. The remaining
181 two patients' charts did not include information about their sternal pain after
182 SABR.

183

184 There were no grade 3/4 acute or grade 3/4 late toxicities (Table 4). Four
185 patients developed acute grade 1/2 skin reactions, and two patients had late
186 grade 1 skin reactions. Two patients who had pain prior to treatment reported
187 acute grade 1 pain in the treated area.

188

189 **Discussion**

190 Our case series demonstrates that single fraction SABR to the sternal
191 metastases is a safe and effective treatment for pain and local control in

192 patients with oligometastatic breast cancer. It is a non-invasive alternative to
193 radical surgical resection, with less morbidity and cost.

194

195 The optimal dose and fractionation schedule for treating bone metastases
196 remains controversial. We found that SABR with a dose of 20Gy in 1 fraction to
197 sternal metastases provides good local control. Nine patients had in-field control
198 of their treated sternal metastasis after the completion of SABR, with a local
199 control rate of 90% at 12 months. This is consistent with existing literature
200 showing that SABR is an effective treatment for local control of bone
201 metastases[12, 17]. Spencer et. al conducted a systematic review of 57 studies
202 which showed pain response rates of >75% and local control rates >80%
203 following SBRT for bone metastases[18].

204

205 In our case series, one patient had marginal recurrence and one patient had in-
206 field recurrence, both patients had a PTV size >90cc. We postulate that the
207 marginal recurrence can be attributed to subclinical disease extension not
208 detectable on imaging. Our current institutional policy based on practical
209 consensus is to add a 5mm to GTV and crop within anatomical boundaries to
210 create a CTV. The CTV is then expanded by 5mm to create a PTV. An
211 additional method of reducing the rate of marginal recurrence might be to
212 routinely also use MRI to help delineate bone metastases[19]. However the only
213 patient in this case series who had a CTV of 5mm still developed a marginal
214 recurrence inferior to the PTV. This suggests there might be other contributing
215 factors such as size of sternal metastasis and breast cancer phenotype.

216

217 The two patients in the study who recurred locally were the only patients with
218 triple negative disease. Both developed distant relapse within 6 months after
219 the completion of SABR. and one of them died at 13 months due to distant
220 disease. This is consistent with triple negative breast cancer behaving more
221 aggressively compared to other breast cancer phenotypes. Our case series
222 raises the question on whether there is any additional benefit for SABR to
223 oligometastatic disease in triple negative breast cancer patients. Further studies

224 are needed to determine which subset of patients with oligometastatic breast
225 cancer would benefit from aggressive local therapies.

226

227 Nine out of ten patients in this case series were alive at the time of analysis,
228 with a median follow-up of 32 months. Milano et al. found that some patients
229 with oligometastatic breast cancer treated with hypofractionated stereotactic
230 radiotherapy can survive more than 10 years[20]. Recent trials suggest that
231 treating all sites of oligometastatic disease with SABR is associated with an
232 improvement in progression free survival and overall survival[21, 22].

233

234 SABR to bone metastases is known to provide good and durable pain
235 control[18, 23]. Most of the symptomatic patients in our case series had an
236 improvement in their pain beyond 12 months. A recent prospective randomized
237 single institution phase 2 non-inferiority trial indicated that patients with painful
238 bone metastases who underwent high-dose single fraction SABR (12 or 16Gy)
239 had better pain response than patients who had conventional 30Gy in 10
240 fractions[24]. Additionally a review on the published cost-effectiveness studies
241 on stereotactic radiosurgery (SRS) and SABR has shown that they are cost-
242 effective management strategies when compared with conventional
243 treatment[25]. This further supports the notion of considering SABR in the
244 palliative setting.

245

246 This case series outlines a technique on treating sternal metastasis with
247 stereotactic radiotherapy with excellent local control, using a single dose which
248 is very convenient for patients. There is no reported literature on SABR in
249 sternal metastases. SABR is typically used for spherically shaped volumes,
250 most commonly in the lung. Our data demonstrates that it is also a safe and
251 effective technique for atypically shaped and large volume metastases (PTV
252 range, 14.4cc - 197.8cc).

253

254 Previous publications have indicated that severe toxicity from SABR to bone
255 metastases is rare[18, 23]. Our patients had minimal grade 1 or 2 acute and late

256 toxicities and there were no grade 3 or 4 toxicities. Interestingly the
257 asymptomatic patient with the largest GTV of 103.4cc developed an acute
258 grade 2 skin reaction and no pain. Whereas the patient with the smallest GTV of
259 3.0cc had pain prior to treatment and had ongoing but improved grade 1 pain
260 since treatment.

261

262 Our case series has several limitations. It includes a small number of patients,
263 with varying breast cancer phenotypes and disease burden. Acute and late
264 toxicities were collected retrospectively based on clinical records. Additionally,
265 most of the patients received endocrine and systemic therapy, which would
266 influence the progression and survival outcomes recorded. Given that most
267 breast cancer patients with bone only oligometastatic disease will survive more
268 than 10 years[20], a prospective study with longer follow-up to assess late
269 toxicities and treatment benefit is required. However this small series
270 demonstrates that SABR to sternal metastasis was feasible and has minimal
271 toxicity with medium term local control in all ten patients with median follow-up
272 of 32 months.

273

274 Conclusion

275 Our case series is the first to provide safety and efficacy data on SABR as a
276 management strategy of sternal metastases in patients with oligometastatic
277 breast cancer. It supports the notion that single fraction SABR is a safe
278 treatment that provides effective pain control and local control of bone
279 metastases in selected patients.
