Key Points:

- Surface temperature should be compared with downward infrared radiation and not net infrared radiation
- The Arctic surface temperature trend is driven primarily by downward infrared radiation and not surface turbulent fluxes.
- The downward infrared radiation trend is associated with the intraseasonal moisture intrusion trend.

Abstract

The Arctic has been warming faster than elsewhere, especially during the cold season. According to the leading theory, ice-albedo feedback warms the Arctic Ocean during the summer, and the heat gained by the ocean is released during the winter, causing the cold-season warming. Screen and Simmonds (2010; SS10) concluded that the theory is correct by comparing trend patterns in surface air temperature (SAT), surface turbulence heat flux (HF) and net surface infrared radiation (IR). However, in this comparison, downward IR is more appropriate to use. By analyzing the same data

Author Manuscript

used in SS10 using the surface energy budget, it is shown here that over most of the Arctic the skin temperature trend, which closely resembles the SAT trend, is largely accounted for by the downward IR, not the HF, trend.

1 Introduction

Over the past several decades, the Arctic has been warming more rapidly than other parts of the Earth. This warming is particularly strong during winter. Climate model simulations also show that Arctic amplification is stronger during winter (e.g., Serreze and Francis 2006). The viewpoint of the leading theory on this topic is that when sea-ice area declines during the summer (due to greenhouse gas warming), the ice-albedo feedback mechanism causes more heat to be deposited into the ocean. According to this scenario, this warming of the ocean during the summer hinders the subsequent cold season growth of sea ice (e.g., Serreze et al. 2009; Screen and Simmonds 2010a; Serreze and Barry 2011; Stroeve et al. 2012), and results in a warming of the overlying atmosphere due to an upward flux of the heat deposited in the ocean.

Screen and Simmonds (2010b; SS10 hereafter) set out to test this hypothesis using ERA-Interim data. They examined the October-January-mean 1989-2009 trends in surface air temperature (SAT), sea-ice concentration, surface net infrared radiation (IR), and surface sensible and latent heat fluxes. The surface net IR was defined as downward IR minus upward IR. They found that surface heat flux trend pattern matches reasonably well with the SAT trend pattern, and that the surface net IR trend pattern is weak and does not match with the SAT trend pattern. Based on these findings, they conclude that the IR effect does not play a dominant role and, consistent with the above hypothesis, they conclude that the main cause of the upward SAT trend is the increased upward surface heat flux. The need to discuss this paper was brought to the attention of the first three authors of this paper in the review process of their earlier work (Gong et al. 2017), where they conclude, also with ERA-Interim data, that the December-February-mean Arctic SAT warming trend during the 1991-2010 period can be accounted for mostly by the downward IR trend, with the surface heat flux playing a limited and local role in Arctic amplification. Because this topic is at the heart of the rapid Arctic climate change, we feel that it would be beneficial to reconcile the difference in the conclusions of the

This article is protected by copyright. All rights reserved.

two studies by carefully comparing the findings of SS10 to those in Gong et al. (2017), but using the same data over the identical time period as in SS10.

The SAT is a commonly used variable in climate studies, yet it is the skin temperature, T_s, which can be readily interpreted in terms of surface energy balance. Following equation (1) of Lesins et al. (2012), but including the storage term G $\left(= \int_0^{\delta z} \rho c_p (\frac{dT_s}{dt}) dz\right)$, where δz is the thickness of a thin interface, and the other variables are standard, the surface energy budget may be written as

$$G = S_d + S_u + I_d + I_u + F_{sh} + F_{lh} + R, \quad (1)$$

where S and I are shortwave and longwave radiation, and the subscript *d* denotes downward and *u* upward. F_{sh} is the surface sensible heat flux, F_{lh} is surface latent heat flux, and the residual R includes heat conduction through sea ice, heat loss (gain) through the melting (freezing) of sea ice, and over the open ocean. R also includes the turbulent heat flux due to mixing in the ocean boundary layer, and horizontal heat flux convergence associated with ocean currents. The atmospheric energy fluxes are defined as positive if they are directed downward (toward the interface); while R is defined positive if the conduction/flux is directed upward (again toward the interface). The interface can be understood as encompassing a very thin layer of air above the surface and a very thin layer of either soil, water, snow or sea ice below the surface. For the atmospheric part of this thin layer, it can be seen as corresponding to the very thin layer above the surface (a few millimeters thick) where heat transport by molecular conduction is stronger than that by turbulent heat fluxes (Wallace and Hobbs 2006). It is important to note that a typical storage layer extends downward to a depth where the temperature undergoes little change. Therefore, the temperature in a typical storage layer differs from T_s. However, because the storage layer is infinitesimally thin, the average temperature will be extremely close to T_s. Furthermore, because the storage layer includes air and soil, water, snow or sea ice, to be more precise, ρ and c_p in G should include values across the interface.

Taking the differential of both sides in (1), where the differential operator Δ represents the

This article is protected by copyright. All rights reserved.

trend, and neglecting the shortwave flux for the winter season, the equation for the trend in the surface energy budget can be written as

$$\Delta G = \Delta I_d + \Delta I_u + \Delta F_{sh} + \Delta F_{lh} + \Delta R. \quad (2)$$

The storage term G is vanishingly small because an infinitesimally thin (δz being very small) air-surface interface has a very small heat capacity (Lesins et al. 2012). Therefore, ΔT_s comes into (2) from the radiative cooling term, that is, I_u. Expressing I_u as $-\varepsilon\sigma T_s^4$ (a minus sign because it is upward) where σ is the Stefan Boltzmann constant and ε the surface emissivity, and taking its differential, equation (2) can be re-written as

$$\Delta T_s = (\Delta I_d + \Delta F_{sh} + \Delta F_{lh} + \Delta R)/(4\varepsilon\sigma T_s^3), \quad (3)$$

where the storage term G has been dropped. Equation (3) tells us that a trend in T_s is associated with trends in downward IR (ΔI_d), ΔF_{sh}, ΔF_{lh} and ΔR. Equation (3) indicates that the trend in T_s (or the trend in the SAT; the daily SAT and T_s are very highly correlated (Chen et al. 2003; $r = 0.97$)) should be compared with the trend in downward IR. The energy budget terms in (3) can be readily computed using available data sets such as ERA-Interim reanalysis.

In comparison, it is challenging to compute the energy budget in terms of the SAT. In this case, one must consider the radiative and heat flux *convergences* into a thin atmospheric layer centered at 2-m above the ground. For the IR radiation, the time rate of change in the SAT is proportional to the sum of the upward energy flux at the bottom of the layer minus the upward energy flux at the top of the layer, and the downward energy flux at the top of the layer minus the downward energy flux at the bottom of the layer. Neglecting shortwave radiation (for Arctic winter), the flux convergence is then

$$(I_{U,B} - I_{U,T}) + (I_{D,T} - I_{D,B}) + (F_B - F_T), \quad (4)$$

where $I_{U,B}$ is upward IR, $I_{D,B}$ is downward IR, and F_B is the sum of the sensible and latent turbulent energy fluxes at the *bottom* of the layer; $I_{U,T}$ is upward IR, $I_{D,T}$ is downward IR, and F_T is the sum of

This article is protected by copyright. All rights reserved.

the sensible and latent turbulent energy fluxes at the *top* of the layer. These energy budget terms are much more difficult to evaluate than the surface energy budget terms. In SS10, an explicit energy balance equation was not used. However, in Fig. 2 of SS10, they do compare $\Delta(I_d - I_u)$ and $\Delta(F_{sh} + F_{lh})$, which are terms in the surface energy balance. Because the bottom of the layer at 2-m faces the surface, if we assume that $I_{D,B} = I_d$, $I_{U,B} = I_u$, and $F_B = F_{sh} + F_{lh}$, then the comparison between $\Delta(I_d - I_u)$ and $\Delta(F_{sh} + F_{lh})$ amounts to a comparison between $\Delta(I_{D,B} - I_{U,B})$ and ΔF_B. We see from (3) and (4), it is incorrect to consider the net surface IR as the IR forcing term even for the SAT.

Although the daily SAT and T_s are highly correlated, for longer time scales, it is possible that the correlation is smaller, especially over regions with a strongly stratified boundary layer. However, as we show in Figs. 1a and 1b, over most of the Arctic, ΔT_s and ΔSAT remain comparable in their pattern and magnitude. (In the ERA-Interim dataset, T_s is calculated from the surface energy balance (https://www.ecmwf.int/en/about; ECMWF Part IV, Physical Processes.) A notable exception is found over the Greenland Sea and the southern part of Barents Sea where $\Delta(SAT - T_s)$ is slightly positive (not shown). These regions are mostly ice free, and as will be revisited in Section 3, the cooling trend in T_s is likely caused by turbulence flux in the ocean mixed layer. Given the overall agreement between ΔT_s and ΔSAT, we evaluate the terms in (3) and attempt to reconcile the conclusion of SS10 and that of Gong et al. (2017).

2 Data and Methods

In this study, we compute the energy budget terms in (3) using the same data source (ERA-Interim data) for the same months (October-January) and time period (1989-2009) as SS10. For the surface and radiative fluxes, daily accumulated values at time steps 3 and 6 for 00:00UTC and 12:00UTC are used. For each UTC, the fluxes are obtained by computing the difference between the step 6 and step 3 forecasted values, and by dividing this difference by the time interval in seconds. The resulting 00:00UTC and 12:00UTC forecasted flux averages are then averaged to obtain the daily surface and

This article is protected by copyright. All rights reserved.

radiative flux values. The ERA-Interim does not provide the heat conduction term, *C*. Therefore, this term is omitted in our analysis.

3 Results

3.1 The Budget Analysis

Figure 1c-e, respectively, shows $\Delta I_d/4\varepsilon\sigma T_s^3$, $(\Delta F_{sh} + \Delta F_{lh})/4\varepsilon\sigma T_s^3$, and $(\Delta I_d + \Delta F_{sh} + \Delta F_{lh})/4\varepsilon\sigma T_s^3$. The surface emissivity ε is set to 1 and at each grid point the October-January mean values averaged over the 21-year period are used for T_s in the denominator. Because ε is in the denominator of the right-hand-side of (3), the relative importance of the various surface flux terms does not depend on its specific value. By comparing panels 1c-e with panel 1a, it is evident that the downward IR term, $\Delta I_d/4\varepsilon\sigma T_s^3$, is the largest term on the right-hand-side of (3). The trends in panels 1a and 1c are positive over virtually all regions in the Arctic.

The surface heat flux trend in Fig. 1d, $(\Delta F_{sh} + \Delta F_{lh})/4\varepsilon\sigma T_s^3$, is more complex: there are positive trends over the Greenland Sea (although statistical significance is marginal in this region) and over most of the Barents Sea, indicating trends of anomalous atmosphere-to-surface heat fluxes in this region. This particular region is masked in Figs. 2c-e of SS10 by gray shading. (Although not mentioned in SS10, the intention of the masking was to focus on ice-covered regions.) Therefore, a comparison with SS10 cannot be made for this region. Over other parts of the Arctic Ocean, the flux trend is negative, i.e., a surface heat flux trend from the surface to the atmosphere. This trend field (Fig. 1d) compares very well with Fig. 2e of SS10. (Note that their sign convention for the surface heat flux is opposite to ours. In SS10, positive values indicate an upward flux.) SS10 concluded that the upward surface heat flux is the dominant driver of the SAT. However, over those parts of the Arctic where the surface heat flux trend is negative, i.e., an upward heat flux trend, with the exception of small parts of the Chukchi and Kara Seas, Fig. 1e shows that the magnitude of the surface heat flux trend is smaller than that of the downward IR trend. Therefore, the results of our analysis are at odds

This article is protected by copyright. All rights reserved.

with the conclusions of SS10, and indicate that the downward IR is the dominant, not a minor, contributor to the winter SAT and skin temperature increase.

The sum of the downward IR and surface heat flux trends, i.e., $(\Delta I_d + \Delta F_{sh} + \Delta F_{lh})/4\varepsilon\sigma T_s^3$ (Fig. 1e) show a close match with the skin temperature trend, i.e., ΔT_s (Fig. 1a), over most of the Arctic. Those regions where these trends differ can be identified by subtracting $(\Delta I_d + \Delta F_{sh} + \Delta F_{lh})/4\varepsilon\sigma T_s^3$ from ΔT_s (Fig. 1f). This difference between these two trends is the residual, i.e., $\Delta R/(4\varepsilon\sigma T_s^3)$ in (3). As can be seen, the residual is largest over the Greenland, southern Barents and Chukchi Seas. During the winter season, the Greenland and southern Barents Seas lack sea ice coverage, whereas the Chukchi and the northern part of the Barents and Kara Seas are mostly ice covered, although as shown in SS10 it is these seas that underwent the largest decline in sea ice. As discussed above, over the ice-covered parts of the Arctic Ocean, $\Delta R/(4\varepsilon\sigma T_s^3)$ can correspond to the trend in conduction of heat through the sea ice. On the other hand, for open water, $\Delta R/(4\varepsilon\sigma T_s^3)$ corresponds to a trend in the turbulent vertical heat flux due to mixing in the ocean, in addition to horizontal heat transport trend by ocean currents. The largest values of the residual in Fig. 1f are consistent with a thinning of sea ice over the Chukchi Sea, and therefore an increase in upward heat conduction. For the Greenland and southern Barents Seas, it is consistent with a downward turbulent heat flux from the ocean surface into the mixed layer, which offsets the warming of the ocean surface due to the positive trend in both the downward IR (Fig. 1c) and downward surface heat fluxes (Fig. 1d). In regions of perennial sea ice cover over the central Arctic, the residual has a weak but statistically significant negative trend, indicating less heat conduction through the ice. This is consistent with an increase of the skin temperature (Fig. 1a) because a decreasing temperature gradient between the ice surface and ice bottom will lead to less upward heat conduction.

The dots show values that are statistically significant at the $p < 0.10$ level for a Student's t-test.

3.2 A cause of the downward IR trend

Given the results of the above budget analysis, a natural question to ask is what causes the downward IR to increase. Gong et al. (2017) and others showed that the intraseasonal midlatitude winter circulation is an important contributor to the downward IR increase on the same time scale (Doyle et al. 2011; Lee et al. 2011; Yoo et al. 2012a,b; Woods et al. 2013; D.-S. Park et al. 2015; H.-S. Park et al. 2015; Woods and Caballero 2016; Baggett et al. 2016; Luo et al. 2017). Doyle et al. (2011)

This article is protected by copyright. All rights reserved.

analyzed in-situ data in the high Arctic and speculated that increases in warm moist air intrusions into the Arctic could contribute to long-term warming over the Arctic. Lee et al. (2011) showed that more frequent occurrences of particular intraseasonal teleconnections have contributed to long-term Arctic warming through their impact on downward IR. Yoo et al. (2011) showed that the more frequent occurrence of a certain phases of the Madden-Julian Oscillation (MJO) contributed to the Arctic warming. Along the same lines, D.-S. Park et al. (2015), Woods and Caballlero (2016), and Gong et al. (2017) showed that a long-term increase in the intraseasonal moisture intrusions into the Arctic can help account for the positive trend in the downward IR during the winter season over recent decades. Gong and Luo (2017) showed that more frequent Ural Blocking is associated with the sea-ice decline in the Barents-Kara Seas. Therefore, we test if the above process occurs for the same data as in SS10.

To examine if a similar process is involved for the trends in the present study, as in D.-S. Park et al. (2015) and Gong et al. (2017), we construct a daily IR index by projecting the daily downward IR field onto the inter-decadal (1989-2009) downward IR linear trend pattern in Fig. 1b. The projection domain is poleward of 70ºN. (The 70ºN latitude is indicated by the thick circle in all of the figures presented in this study.) With this downward IR trend projection time series, which we denote as x, one can obtain an associated trend of any variable, y, at any grid point. The linear trend of y associated with the trend of x, $\Delta_x y$, can be written as

$$\Delta_x y(\tau) = [\mathrm{r}(\tau)\, \sigma(y)/\sigma(x)]\Delta x \qquad (4)$$

where Δx is the 1989-2009 linear trend in x, $\mathrm{r}(\tau)$ is the linear correlation between the *daily* values of $x(t)$ and $y(t+\tau)$ for time lag τ, and $\sigma(x)$ and $\sigma(y)$ are the standard deviations of x and y, respectively. In (4), the quantity $\mathrm{r}(\tau)\sigma(y)/\sigma(x)$ is the lagged regression coefficient. For our calculation of $\mathrm{r}(\tau)$, as in Gong et al. (2017), the October-December mean values of *x* and *y* are subtracted for each year. Equation (4) was constructed from the perspective that the intraseasonal relationship between *x* and *y*, in combination with the trend in *x*, contributes to the linear trend in *y*.

This article is protected by copyright. All rights reserved.

We also consider time lags to examine the lag-lead relationship between x and y. We denote the trend of y associated with the linear trend of x as $\Delta_x y$ to distinguish it from its linear trend, Δy. In particular, it needs to be recognized that the downward IR trend associated with x, $\Delta_x I_d$, can be different from its own linear trend ΔI_d.

Consistent with the findings by D.-S. Park et al. (2015) and Gong et al. (2017), we see that within the 10-day interval leading up to local peak in x, there is an enhanced moisture flux convergence (multiplied by the latent heat of vaporization, L) trend into the Arctic (Fig. 2a). The region with largest convergence occurs over the Greenland and Barents Seas where the surface heat flux trend is from the atmosphere to the surface (Fig. 1c). Since the contribution to anomalies in downward IR by liquid water and ice is much greater than that by water vapor (Eugene Clothiaux, personal communication), we also calculate the trends in the total column-integrated ice and liquid water (Fig. 2b) and downward IR (Fig. 2c). As can be seen, the spatial pattern of the moisture flux convergence (multiplied by L) trend resembles that of both the total column liquid water plus ice and downward IR, and has an amplitude of about one half that of the downward IR. These findings suggest that moisture fluxes from the midlatitudes into the Arctic are an important contributor to the downward IR trend poleward of 70ºN.

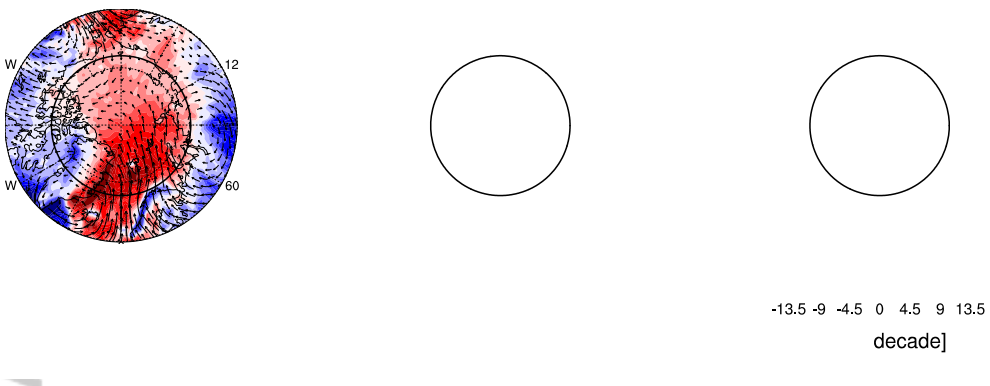

Figure 2: The trends for selected moist thermodynamic variables obtained by multiplying the regression

This article is protected by copyright. All rights reserved.

coefficients (regression against the IR index) and the trend in the IR index. Trends are shown for the vertically integrated moisture flux vectors and moisture flux convergence multiplied by the latent heat of vaporization, L (L*MoisFluxconv; a), total column condensed water (liquid water plus ice) (TCIW+TCLW; b), and the downward IR (downward IR; c). The lag chosen for TCIW+TCLW and downward IR is lag 0 days, and the average of the lag day -10 through lag day 0 trends for the moisture flux. The dots indicate values that are statistically significant at the $p < 0.10$ level for a Student's t-test.

As shown above (Fig. 2), although moisture flux convergence is an important contributor to the downward IR trend, Fig. 1d implies that an increase in evaporation could also be a substantial contributor to the downward IR trend over the Chukchi and Kara Seas. Integrating over the region north of 70N, we find that the moisture flux convergence trend is 7.6×10^6 m^3 $decade^{-1}$, while the evaporation trend is much smaller and negative, -0.7×10^6 m^3 $decade^{-1}$. From this analysis, we conclude that averaged over the entire Arctic Ocean, moisture flux convergence played the dominant role in enhancing total column water accumulation over the cold season and thus downward IR.

3.3 Intraseasonal evolution of the surface energy budget

Given the evidence that the intraseasonal time-scale circulation plays an important role in increasing the Arctic T_s (and SAT), it is insightful to examine the time evolution of the budget terms to gain a better understanding of the physical processes. Figure 3 shows $\Delta_x y(\tau)$ for various y and τ. It can be seen that downward IR ($\Delta_x I_d(\tau)$, first column) gradually increases from lag day -10 to day 0, and then declines afterwards. The upward IR ($\Delta_x I_u(\tau)$, second column) pattern is almost identical to the downward IR pattern, except that for most lag days it is somewhat weaker; the total IR (downward minus upward) is positive for all lags throughout the Arctic except for lag +10 days (third column). The Arctic $\Delta_x T_s(\tau)$, and $\Delta_x SAT(\tau)$ are positive, reaching their maximum values at $\tau = 0$. (These two fields are almost identical at all τ shown, again supporting the idea that budget equation (3) can be used to understand the SAT trend.) These results suggest that as warm moist air enters the Arctic (Fig.

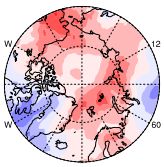

This article is protected by copyright. All rights reserved.

2a), downward IR first warms the surface, and in response, there is an increase in the upward IR emitted by the surface.

The surface heat flux (fourth column) adds to this picture: at negative lags, it is notably downward over the Greenland and most of the Barents Seas, indicating that there is anomalous heat transfer from the atmosphere to the surface in these seas. The downward flux builds up to lag zero ($\tau = 0$) and then declines. By lag +5 days for the Kara Sea, and lag +10 days for the Barents Sea, its sign changes and the surface heat flux is upward. We interpret these results to indicate that as warm moist air enters the Arctic, downward IR warms the surface (and melts sea ice where sea ice present); as the intrusion event comes to an end, the surface heat flux turns upward.

4 Discussion and Conclusions

In this study, we revisited the analysis of SS10 by performing surface energy budget analysis. This investigation leads us to conclude that downward IR played the leading role in warming the Arctic over most of the Arctic Ocean for the same the months (October- January) and years (1989-2009) as examined by SS10. We surmise that the overall discrepancy arises because in SS10 the net IR was compared to SAT. However, upon noting that the heat storage is negligible for a thin interface, and expressing the upward IR trend in terms of the skin temperature trend, the correct comparison is between the skin temperature trend (very similar to the SAT trend) and the downward IR trend, not the net IR trend, and the surface heat flux trends.

Over most of the Barents Sea, which may be regarded as a marginal sea ice zone, the surface heat flux trend is strongly downward, i.e., a turbulent heat transfer trend from the atmosphere to the ocean. The intraseasonal evolution of the surface fluxes reveals that the surface heat flux in this region changes sign and turns upward after downward IR heats the surface. Similar behavior was shown by D.-S. Park et al (2015), Woods and Caballero (2016), and Gong et al. (2017). Therefore, at least in this region and during the time period that we examined, the conventional picture that the surface warming is caused by turbulent heat flux from the ocean (be it the ice-albedo feedback during sun-lit seasons or an enhanced influx of warm water from the North Atlantic) does not hold up.

Over the Chukchi, Laptev, and Kara Seas, the heat flux trend is upward, presumably reflecting the effect of declining sea-ice cover and ice thickness. Especially over the Chukchi Sea and a small area of the Kara Sea, the upward heat flux trend is greater than the downward IR trend. This upward heat flux trend could be caused by ocean warming during the sunlit season when ice-albedo feedback can contribute to the warming. For the Chukchi Sea, this upward heat flux trend could also be caused by changes in the warm current from the Pacific Ocean (Shimada et al. 2006; Peralta-Ferriz et al. 2014).

Author Manuscript

This article is protected by copyright. All rights reserved.

It was shown that the downward IR trend is associated with a trend in the moisture fluxes from midlatitudes into the Arctic, as well as a trend in the total column liquid water and ice in the Arctic. Gong et al. (2017) showed that this moisture flux trend arises from a trend in synoptic time scale intrusions of moisture into the Arctic. Therefore, the results of this study imply that synoptic-scale moisture intrusion events, via their impact on downward IR, have a very large impact on the Arctic warming. However, over parts of the Chukchi and Kara Seas, where the surface heat flux trend is upward and with a larger magnitude than the downward IR trend, hence it is possible that the positive SAT trend arises from an upward sensible and/or latent heat flux, as well as an increase in the downward IR due to the input of additional water vapor into the atmosphere. (Note that an upward sensible heat flux will, per se, reduce the skin temperature (cf. eq. (2)). However, since the skin temperature trend (Fig. 1a) and the SAT trend (SS10) both showing a warming trend over the Chukchi and Kara Seas, the implication is that the skin temperature increase is due to conduction from below the surface and an increase in downward IR.) It is possible that in these two seas this process may dominate the impact of warm moist air intrusions. Further research with the horizontal sensible and latent heat flux convergence, together with radiative transfer calculations, should be able to clarify this issue.
