Concerns about increasing concentrations of greenhouse gases in the atmosphere, primarily carbon dioxide (CO₂), have raised worldwide interest in the potential of agricultural soils to be carbon (C) sinks. In Australia, studies that have quantified the effects of improved management practices in croplands on soil C have generally been inconclusive and contradictory for different soil depths and durations of the management changes. We therefore quantitatively synthesised the results of Australian studies using meta-analytic techniques to assess the technical and economic feasibility of increasing the soil C stock by improved management practices. Our results indicate that the potential of these improved practices to store C is limited to the surface 0–10 cm of soil and diminishes with time. None of these widely adopted practices is currently financially attractive under Australia's new legislation known as the Carbon Farming Initiative.

Globally, soils are estimated to contain 1500 Pg of soil organic carbon (C) to a depth of 1 m, approximately double the amount of C in the atmosphere¹. Around 160 Pg of organic C are stored in soils of agricultural croplands in the world¹. A meta-analysis showed that long-term conversion of native forest and pasture to cropland has reduced soil organic C stocks by an average of 42% and 59%, respectively². By adopting improved agricultural management practices, agricultural soils in the world are estimated to have the potential to sequester 0.4–0.8 Pg C per year³.

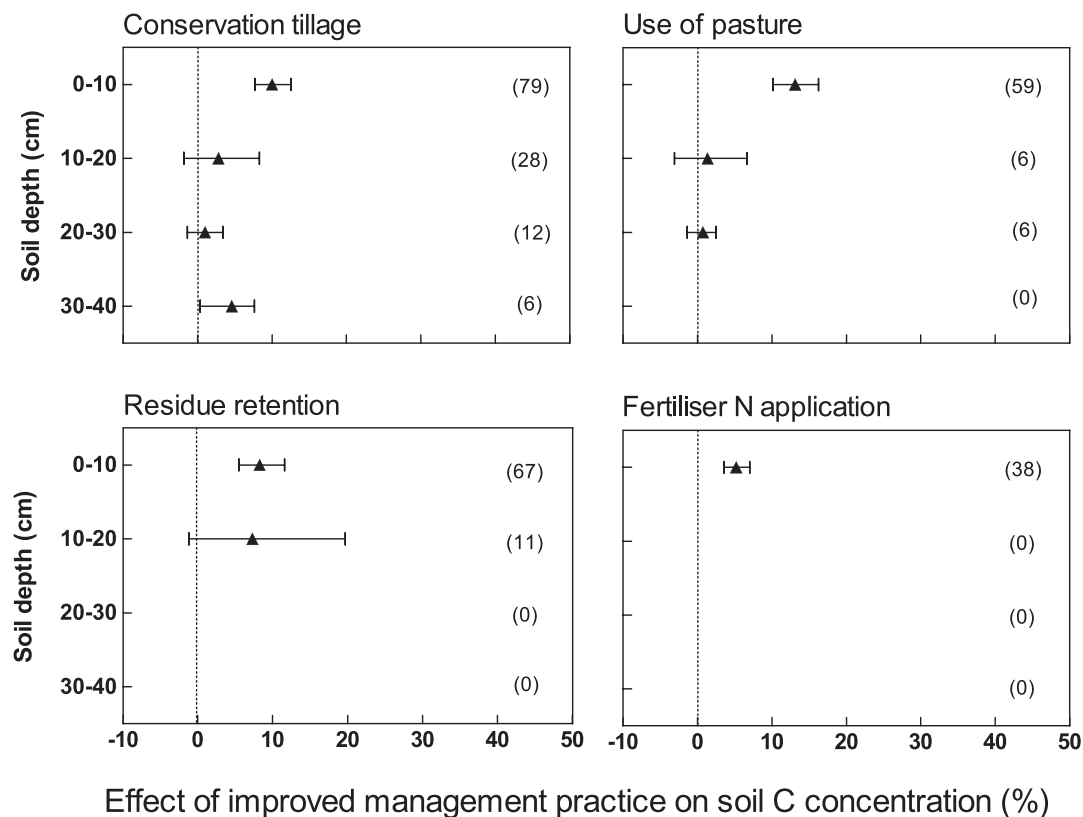

Improved agricultural management practices such as conversion from conventional to no-till or reduced tillage, residue retention, conversion to permanent pasture, crop rotation and fertiliser application have been shown to increase soil C in various countries, including Australia^{4–6}. However, contradictory results are common in the literature. For example, a meta-analysis based mostly on studies in North America and South America indicated that adoption of no-till did not increase soil C stock down to 40 cm (ref. 7), and the potential for C accrual following conversion from crop to pasture decreased with soil depth². Carbon sequestration rates under different grassland management practices have been demonstrated to vary substantially over time⁴.

Large and continuous inputs of organic matter are conducive to increasing soil C content⁸. The net primary productivity of most of Australia's agricultural land, which determines the potential C input, is water and nutrient limited⁹. Soil C concentrations in Australia are inherently low, except for limited areas under higher rainfall along the east coast⁵. The range of soil C in the upper 1 m of soil in Australia is 18–447 Mg ha⁻¹, compared to a global value of 30–800 Mg ha⁻¹ (ref. 8). While the impacts of agricultural management practices on soil C sequestration potential in Australia have been reviewed^{5,9}, a quantitative synthesis of the responses of the soil C stock to these practices for a range of soil depths and years of implementation is lacking.

This information is important for assessing the potential of improved management practices to increase C storage, or reduce C loss, within soil profiles and over time. Farmers and land managers need this information to determine whether they can earn carbon credits under Australia's Carbon Farming Initiative (CFI), which was launched to create a financial incentive for the adoption of management practices that store soil C permanently (100 years or more) and improve the soil condition and hence its productivity¹⁰.

The carbon and nitrogen (N) cycles are tightly coupled¹¹. The C:N ratio of agricultural soils generally maintains a constant narrow range, with an average of 10:1⁸. Thus, N is required to stabilise agricultural soil C accrual⁶. However, the cost of N for C storage is often overlooked in assessing the benefit of C credit earned from improved management practices.

We therefore conducted a meta-analysis of published data on the responses of soil C to improved agricultural practices, viz. conservation tillage, residue retention, the use of pasture, and fertiliser N application. The objectives of this analysis were (i) to quantify the changes in soil C concentration and soil C stock under improved

Effect of improved management practice on soil C concentration (%)

Figure 1 | Effect of improved management practices on soil C concentration at various soil depths. Means and 95% confidence intervals are depicted. Numbers of experimental observations are in parentheses. The database of the meta-analyses can be found as Supplementary Tables S1–S4 online.

management practices, with respect to soil depth and management duration; and (ii) to provide a simple assessment of the economic feasibility of these practices.

Results

Effect of improved management practices on soil C at various soil depths. Soil C concentration in the surface soil layer (0–10 cm) was significantly greater under conservation tillage (by 10%), residue retention (by 8%), the use of pasture (by 13%) and fertiliser N application (by 7%), when compared to control treatments (Fig. 1). Soil C stock in surface soil (0–10 cm) was higher under these management treatments than in the untreated controls. The relative gain in soil C stock in this surface layer was in the order of: pasture use ($140 \text{ kg C ha}^{-1} \text{ year}^{-1}$) > conservation tillage ($139 \text{ kg C ha}^{-1} \text{ year}^{-1}$) > residue retention ($62 \text{ kg C ha}^{-1} \text{ year}^{-1}$) > fertiliser N application ($47 \text{ kg C ha}^{-1} \text{ year}^{-1}$) (Table 1). Neither soil C concentration or soil C stock was significantly increased by these management in soil deeper than 10 cm (Fig. 1; Table 1).

Effect of improved management practices on soil C under different experimental durations. The four management practices significantly increased soil C concentration for at least 20 years after the treatments began (Fig. 2). These increases were averaged across soil depths, but were reflective of the changes occurring mostly in the 0–10 cm layer (Fig. 1). While the effects on soil C concentration of residue retention (2–10%) and fertiliser N application (3–7%) decreased with time, those for conservation tillage (7–10%) and pasture use (10–13%) were sustained longer (Fig. 2). The annual relative gain in soil C stock was greatest during the first 10 years after implementation of improved management treatments, when the increases were in the order of: conservation tillage ($150 \text{ kg C ha}^{-1} \text{ year}^{-1}$) > residue retention ($147 \text{ kg C ha}^{-1} \text{ year}^{-1}$) > pasture use ($132 \text{ kg C ha}^{-1} \text{ year}^{-1}$) > fertiliser N application (67 kg C ha^{-1}

year^{-1}) (Table 2). These increases correspond to a soil C gain of 247–552 $\text{kg CO}_2\text{-equivalent (CO}_2\text{-e) ha}^{-1} \text{ year}^{-1}$ during the first 10 years of implementation of the improved management practices (Table 2).

Economic assessment. The relative soil C gain represents a carbon credit of AUD $1.8 \text{ ha}^{-1} \text{ year}^{-1}$ by practising conservation tillage,

^acalculated for a carbon price of USD 3.35 (AUD 3.19) Mg⁻¹ CO₂-equivalent in the voluntary carbon market³², based on exchange rate of AUD: USD = 1 : 1.05.

^bcalculated for a Kyoto Australian carbon credit unit of AUD 23 Mg⁻¹ CO₂-equivalent issued under the Carbon Farming Initiative (CFI) in Australia¹⁰.

^cestimated by soil C:N ratio of 10 : 1 (ref. 8).

^destimated by N cost of AUD 600 Mg⁻¹ urea (46%N)³³.

AUD 1.7 ha⁻¹ year⁻¹ for residue retention, AUD 1.5 ha⁻¹ year⁻¹ for the use of pasture, and AUD 0.8 ha⁻¹ year⁻¹ for fertiliser N application, during the first 10 years of a management change (Table 2). When the cost of N to stabilise C storage was considered, the financial loss based on the C price in the voluntary carbon market was AUD 17.8 ha⁻¹ year⁻¹ for conservation tillage, AUD 17.5 ha⁻¹ year⁻¹ for residue retention, AUD 15.7 ha⁻¹ year⁻¹ for pasture use, and AUD 8.0 ha⁻¹ year⁻¹ for fertiliser N application (Table 2). Based on the CFI, the financial loss was reduced to AUD 6.9, 6.8, 6.1 and 3.1 ha⁻¹ year⁻¹ correspondingly (Table 2).

Discussion

Based on the available field studies that covered a wide range of soil and climatic conditions across Australia, our results suggest that soil at 0–10 cm depth is the most responsive to the targeted management practices in Australia's cropped soils. Increases in soil C as a result of these management practices have been attributed to enhanced biomass (above- and below-ground) production, litterfall and hence return of residues to the soil, and also to improved soil aggregation that protects the C compounds from rapid decomposition^{4,6,12}. However, the small increases (7–13%) in the C concentration in the surface layer of Australian agricultural soils may not be technically credible due to sampling errors, spatial variability and uncertainties associated with measurement and analysis¹³. The positive management effects on soil C concentration or C stock were not detectable in soil deeper than 10 cm (Fig. 1; Table 1). This result is not unique to Australian cropping systems. For example, in studies comparing conservation tillage with conventional tillage in other countries, it has been shown that soil C may increase only in the surface 10 cm of the soil, and remain unchanged or even decrease in deeper layers^{7,14}.

Carbon accumulation can be increased in the surface 0–10 cm of soil, but that is also the layer from which it can be most readily lost from Australian agricultural soils⁵, and the management-induced increases of soil C in this surface layer are very vulnerable to environmental and management pressures⁹. It is therefore necessary to examine whether an agricultural practice sustains surface soil C over time. This is important because the intent of Australia's CFI is to encourage farmers and land managers to use an approved methodology that enables permanent storage of soil C (100+ years)¹⁰. However, we found that the relative soil C gain in Australian cropping systems decreased with time, regardless of agricultural practices (Table 2). Moreover, soil organic C in many Australian cropping soils is not in state of C equilibrium, and the soils are continuing to lose C¹⁵. The observed relative C gain under improved management treatments might therefore have resulted from a reduced or discontinued soil C loss instead of real C accrual¹⁵.

In terms of sustainability, the use of pasture outperformed the other practices after 31–40 years (Table 2). This highlights the potential use of pasture in C sequestration in Australian agriculture, for at least 40 years. However, at least three problems must be considered with increased pasture use, especially permanent pasture, in Australia: (i) increased methane emissions for ruminant animals grazing those pastures, (ii) the extra demand for irrigation water to maintain those pastures (if they are to be effective in storing more soil C), and (iii) the less efficient use of solar radiation per hectare in producing food from animals compared to food from crops.

When the cost of N to stabilise C accrual was considered, we estimated that none of the four management practices resulted in any net profit based on the recent C trading price of AUD 3.19 Mg⁻¹ CO₂-e in the voluntary market, but a loss of AUD 8–18 ha⁻¹ year⁻¹ for the first 10 years of implementation of the practice (Table 2). The loss was reduced to AUD 3–7 ha⁻¹ year⁻¹ under the CFI in Australia (currently at AUD 23 Mg⁻¹ CO₂-e). The minimum C price required for a net profit was estimated to be AUD 36 Mg⁻¹ CO₂-e. These results indicate that current agricultural management options and

the current value of conserved C are not economically viable. More importantly, for a carbon trading scheme to be credible, change in soil C has to be verifiably measured or modelled cost-effectively at the farm scale¹³.

In terms of benefits to the environment, based on an area of approximately 100 M ha of managed cropland and modified pasture in Australia in 2006 (ref. 16), we estimate that the gain in CO₂-e equates to 4.6–10.3% of total national greenhouse gas (GHG) emissions in the same year of 533.1 Tg CO₂-e¹⁷. This estimate assumes 100 percent take-up of the improved practices and does not consider the potential impact of these practices on emissions of methane from grazing animals and nitrous oxide from additional N fertiliser use^{18–21}. While the effects of improved management practices on soil C stock vary with temperature and rainfall⁵, scientific knowledge of the capacity of the soil to store C under future climates, such as warmer and drier conditions and higher atmospheric CO₂ levels^{22–24}, is insufficient for Australian cropping systems.

Our analysis shows that improved management practices (conservation tillage, residue retention, the use of pasture or fertiliser N application) increased soil C by 0.05–0.15 Mg C ha⁻¹ year⁻¹ only in the surface 10 cm of Australian croplands. The effects were more pronounced during the first 10 years of implementation of improved management practices.

Because of the technical uncertainty in measuring small soil C changes, and the higher cost of stabilising any gain in soil C compared with the C credit earned, carbon sequestration in Australian agricultural soils as a means of offsetting a significant part of the national GHG emissions is technically limited and economically nonviable at the present time. These results have major implications for improvement in the measurement and modelling of soil C changes at the field scale, and enactment of carbon reduction legislations in Australia and other parts of the world.

Methods

Database compilation. This meta-analysis is based on studies (see Supplementary Notes online) of the effects of agricultural land management practices (conservation tillage, residue retention, the use of pasture, and N fertilisation) on soil C concentration (%C) and C stock (kg C ha⁻¹) in Australian cropping systems published between 1984 and December 2012. We performed extensive keyword searches of several databases (Web of Science, CAB Abstracts, Scopus, Agricola and Agriculture and Natural Resources Index), and by examining the reference lists of cited references. The search terms are listed in Supplementary Notes online. Original data were extracted from tables whereas data values presented in figures were obtained using digitizing software.

The following criteria were set for a study to be included in the analysis. First, the sample sizes and means of soil C concentrations or stocks had to be reported for control and treatment plots. Second, treatments were applied at the same farm site throughout the experimental period, i.e. paired-site studies or surveys were excluded. Third, the study must have been conducted under field conditions for at least three consecutive years. For multiple observations at any one site over time, individual observations were selected at intervals of at least every third year. The duration of an experiment was considered as the number of years after the commencement of a treatment. Conservation tillage encompassed no-till and reduced tillage. Residue retention comprised the incorporation of residues and surface retention. The use of pasture included conversion of cropped land to pasture and the incorporation of pasture into a rotation.

Because the soil C stock is an amount of C in a mass of soil in a defined area (1 ha) to a defined depth (commonly 30 cm), C concentration must be multiplied by the dry bulk density (BD) to obtain the soil C stock (kg ha⁻¹). Hence when not reported, soil C stock was calculated by multiplying the %C values for each soil depth interval by its BD and the depth increment. In experiments where BD was not provided, a pedotransfer function was used to estimate BD. For the studies included in this meta-analysis, we considered two published pedotransfer functions for the estimation of BD by comparing the regression between measured and estimated BD values. The two functions were BD = 1.66–0.308 (OC)^{0.5} (equation (1)²⁵) and BD = 1.398–0.0047 (%Clay)–0.042 (%OC) (equation (2)²⁶), where the BD units were Mg m⁻³ and OC = organic carbon (%). Based on equation (2), the regression coefficient between measured and estimated BD values was 0.64 ($p < 0.001$), whereas that based on equation (1) was 0.32 ($p < 0.001$). We therefore based our estimation of BD on equation (2).

Ideally, the soil C stock for treatments and controls should be compared on an equivalent mass, rather than a fixed depth basis, because of the changes in BD that may occur under different management practices²⁷. In our study, soil depth was not adjusted to account for changes, if any, in BD associated with changes in management practices unless the authors of the study had already done so. Not adjusting soil depth

may in some cases result in a small error in the estimate of the management effects on soil C stocks per unit land area²⁸.

The database of the meta-analyses is in Supplementary Tables S1–S4 online. The dataset was compiled from 56 studies with 435 direct comparisons, including 172 comparisons for the effects of conservation tillage, 116 for residue retention, 83 for the use of pasture and 64 for fertiliser N application. The potential patterns of variation in the effects of various management practices were also assessed by including categorical variables in the meta-analysis models. These variables included experimental duration (0–10, 11–20, 21–30 and 31–40 years) and soil depth (0–10, 10–20, 20–30 and 30–40 cm). Soil sampling depths varied between studies. For studies in which the sampling depths did not match the defined categories, each data point for C concentration was categorised as the average depth of the soil layer from which it was collected¹⁴. Soil C stock data were included only if the sampling depth matched the defined categories.

Meta-analysis. We used the natural log of the response ratio ($r = \bar{x}_t/\bar{x}_c$, where \bar{x}_t and \bar{x}_c are the means of the treatment and control groups, respectively)²⁹ as a metric for the analysis of treatment effects on soil C concentration. These results are reported as the percentage change under treatment effects ($(r - 1) \times 100$). Negative percentage changes indicate a decrease in soil C compared with the control and positive values indicate an increase due to an improved management practice. The effect of management practices on the rate of change in the soil C stock relative to the control was expressed as U ($\text{kg C ha}^{-1} \text{ year}^{-1}$) = (amount of C in treatment plot – amount of C in control plot)/experimental duration.

Effect sizes reported in previous meta-analyses on soil C storage were weighted by the inverse of the pooled variance⁶, replication²³ or unweighted². The studies collected in our database did not always include published variances. In addition, the variance-based weighting function could result in extreme weights for some studies, while weighting by replication could yield less extreme weights³⁰. Therefore our analysis was performed on effect sizes weighted by a function of sample size using:

$$\text{weight} = (n_c \times n_t) / (n_c + n_t),$$

where n_c and n_t are the number of replicates of the control and treatment groups, respectively³⁰.

Mean effect sizes and 95% confidence intervals were generated by bootstrapping (4,999 iterations) using MetaWin 2.1³¹. A fixed-effects model or a mixed-effects model is technically not applicable for non-parametric meta-analytic procedures based on weighting by replication. However, to perform correct bootstrapping using MetaWin a fixed-effects model had to be selected. The effects of agricultural management practices were considered significant if the confidence intervals did not overlap with zero.

Economic assessment. We performed an economic assessment of the improved management practices based on the C price of USD 3.35 (AUD 3.19) $\text{Mg}^{-1} \text{CO}_2\text{-e}$ in the voluntary carbon market in 2008 (ref. 32) or Kyoto Australian carbon credit unit at AUD 23 $\text{Mg}^{-1} \text{CO}_2\text{-e}$ in 2013 (ref. 10), a C:N ratio of 10:1 across agricultural soils⁸, and the cost of urea (46% N) at AUD 600 Mg^{-1} (ref. 33). These estimates exclude any increase in N fertiliser cost passed on to the landholder, which is incurred by the manufacturer having to pay the mandatory C price (currently AUD 23 $\text{Mg}^{-1} \text{CO}_2\text{-e}$)¹⁰ associated with GHG emissions during production. The costs of other nutrients such as phosphorus and sulphur to match C gain are not included, nor any of the compliance costs such as reporting and auditing associated with participation in the CFI.

Acknowledgements

We wish to thank Emeritus Professor Robert White and Dr Ian Willett for valuable comments on our manuscript, Dr. Kees Jan van Groenigen for assistance in meta-analytic procedures, and the authors who provided information for the construction of the database. This work was supported by Australian Research Council, Department of Agriculture, Fisheries and Forestry and Dean's strategic research fund of our School.

Author contributions

R.R. and D.C. initiated the concept of the study. R.R., D.C., A.R.M. and S.K.L. designed the investigation. S.K.L. and D.C. contributed to data extraction from the literature and the construction of the database. S.K.L., D.C. and A.R.M. performed the statistical analyses. All authors were involved in writing the paper.

Additional information
