ABSTRACT

Detection of the epoch of reionization (EoR) in the redshifted 21 cm line is a challenging task. Here, we formulate the detection of the EoR signal using the drift scan strategy. This method potentially has better instrumental stability compared to the case where a single patch of sky is tracked. We demonstrate that the correlation time between measured visibilities could extend up to 1–2 hr for an interferometer array such as the Murchison Widefield Array, which has a wide primary beam. We estimate the EoR power based on a cross-correlation of visibilities over time and show that the drift scan strategy is capable of detecting the EoR signal with a signal to noise that is comparable/better compared to the tracking case. We also estimate the visibility correlation for a set of bright point sources and argue that the statistical inhomogeneity of bright point sources might allow their separation from the EoR signal.

1. INTRODUCTION

The dark age of the universe ends with the formation of the first galaxies. The ultraviolet photons from these galaxies start ionizing the neutral H I gas in the universe and form large ionized bubbles. Eventually, these ionized bubbles grow in size and merge until there is no neutral hydrogen left in the universe except in dense optically thick clouds. This major phase transition of the universe is referred to as the epoch of reionization (EoR). Current observational constraints imply that EoR occurred in the redshift range $z \simeq 6\text{--}15$ (Fan et al. 2006; Komatsu et al. 2011).

Apart from the cosmic microwave background radiation anisotropy measurements, which give the integrated optical depth through the reionization epoch, the redshifted 21 cm line transition from neutral hydrogen is the other major probe for studying this epoch. An obvious advantage to the 21 cm probe is that it could reveal the three-dimensional (3D) structure of the EoR. Currently, many radio interferometers are operational with the specific aim of detecting the EoR (Bowman et al. 2006;

Morales 2005; for example, the Murchison Widefield Array (MWA), Bowman et al. 2013; Tingay et al. 2013; LOFAR, Van Haarlem et al. 2013; and PAPER, Parsons et al. 2013). However, detection of the EoR signal is a challenging task for any present day EoR experiments for multiple reasons. First, it is an extremely weak signal (brightness temperature fluctuations $\Delta T_B \simeq 10$ mK) and only a statistical detection of the signal might be possible with the interferometers currently in operation. Second, in the frequency domain 50–250 MHz, both the galactic and extragalactic foregrounds are larger than the observed signal. Major contribution to the foreground comes from the synchrotron emission of relativistic electrons in our Galaxy, radio galaxies, resolved supernovae remnants, free-free emission, and unresolved extragalactic radio sources (Zaroubi 2013). Although radio interferometers focus on fluctuations in the signal, fluctuations in the foreground on relevant angular scales are 10–1000 times higher than the desired cosmological signal.

The statistical detection of the EoR signal requires a stable instrument and a large amount of data to reduce the thermal

noise, in addition to measuring and subtracting the foregrounds. The traditional tracking mode of observation may not be useful for this purpose as it leads to a time-dependent primary beam as the pointing center is moved. In the drift scan technique, the pointing center is fixed at a particular point on the sky and the observation is carried out for a variable sky pattern. One advantage of this technique is the stability of the system (Trott 2014).

In this paper, we describe a methodology based on drift scans which exploits the correlation between visibilities measured at different times to estimate the EoR signal. In particular, our aim is to infer the efficacy of such a method for a wide field-of-view instrument such as MWA.

In the next section, we delineate the basic formalism. In Section 3, we apply the method to the system parameters of MWA. In Section 4, we compute the noise on the estimator of the EoR proposed in this paper and compare the drift scan results with the expected noise in the tracking case. In Section 5, we briefly discuss how our method might potentially allow foregrounds represented by bright point sources to be separated from the EoR signal. In Section 6, we summarize our results.

2. VISIBILITY CORRELATION IN DRIFT SCAN

The basic aim of a radio interferometer is to calculate the spatial correlation of the electric fields from a distant source in the sky. The measured spatial correlation is referred to as “visibility” and is given by

$$V_\nu(\mathbf{U}) = \int A(\boldsymbol{\theta}) I_\nu(\boldsymbol{\theta}) e^{-i2\pi\mathbf{U}\cdot\boldsymbol{\theta}} d\Omega. \quad (1)$$

Here, \mathbf{U} denotes the baseline vector joining a pair of antennas, measured in units of wavelength, projected onto a plane perpendicular to the direction of observation and $\boldsymbol{\theta}$ refers to the position on the sky. $A(\boldsymbol{\theta})$ is the primary beam pattern and $I_\nu(\boldsymbol{\theta})$ is the observed intensity at frequency ν . All other variables have their usual meaning, e.g., Thompson et al. (1986).

In the case of high-redshift H I emission, the specific intensity from any direction $\boldsymbol{\theta}$ at the redshifted frequency $\nu = 1420/(1+z)$ MHz, can be decomposed into two parts:

$$I_\nu(\boldsymbol{\theta}) = \bar{I}_\nu + \Delta I_\nu(\boldsymbol{\theta}), \quad (2)$$

where \bar{I}_ν and $\Delta I_\nu(\boldsymbol{\theta})$ are the isotropic and fluctuating components of the specific intensity.

This allows us to express the visibility arising from H I emission as

$$V_\nu(\mathbf{U}) = \int A(\boldsymbol{\theta}) \Delta I_\nu(\boldsymbol{\theta}) e^{-i2\pi\mathbf{U}\cdot\boldsymbol{\theta}} d\Omega. \quad (3)$$

Here, only the fluctuating component appears since the isotropic component does not contribute to the visibility. We drop the w term when writing the relation between the visibility and specific intensity. We discuss the impact of the w term in Appendix B.

The fluctuating component of H I emission can be expressed in terms of $\Delta_{\text{HI}}(\mathbf{k})$, the Fourier transform of the density contrast of the H I number density $\Delta n_{\text{HI}}(\mathbf{x})/\bar{n}_{\text{HI}}$ (e.g., Bharadwaj & Sethi 2001; Morales & Hewitt 2004):

$$\Delta I_\nu(\boldsymbol{\theta}) = \bar{I}_\nu \int \frac{d^3k}{(2\pi)^3} \Delta_{\text{HI}}(\mathbf{k}) e^{ir_\nu(k_\parallel + \mathbf{k}_\perp \cdot \boldsymbol{\theta})}. \quad (4)$$

Here, k_\parallel and \mathbf{k}_\perp refer to the components of the comoving wavevector \mathbf{k} along the line of sight and in the plane of the

sky, respectively, and r_ν is the comoving distance. With these definitions we can expand the phase term $\mathbf{k}\cdot\mathbf{r}$, as shown in Equation (4). The 3D Fourier transform can be understood as performing a one-dimensional Fourier transform along the line of sight followed by a two-dimensional Fourier transform on the sky plane, or $d^3k = dk_\parallel d^2k_\perp$. Our formulation allows us to treat the integral on the sky plane using Cartesian coordinates, $d^3k = dk_\parallel dk_{\perp 1} dk_{\perp 2}$ (see Equation (15) and Appendix A for details).

Equation (3) can thus be expressed as

$$V_\nu(\mathbf{U}) = \bar{I}_\nu \int \frac{d^3k}{(2\pi)^3} \Delta_{\text{HI}}(\mathbf{k}) e^{ir_\nu k_\parallel} \int d\Omega A(\boldsymbol{\theta}) \times \exp\left[-2\pi i \left(\mathbf{U} - \frac{\mathbf{k}_\perp r_\nu}{2\pi}\right) \cdot \boldsymbol{\theta}\right]. \quad (5)$$

The second integral over the primary beam $A(\boldsymbol{\theta})$ can be denoted as

$$a\left(\mathbf{U} - \frac{\mathbf{k}_\perp r_\nu}{2\pi}\right) \equiv \int d\Omega A(\boldsymbol{\theta}) \exp\left[-2\pi i \left(\mathbf{U} - \frac{\mathbf{k}_\perp r_\nu}{2\pi}\right) \cdot \boldsymbol{\theta}\right]. \quad (6)$$

Thus, finally, Equation (5) takes the following form:

$$V_\nu(\mathbf{U}) = \bar{I}_\nu \int \frac{d^3k}{(2\pi)^3} \Delta_{\text{HI}}(\mathbf{k}) e^{ir_\nu k_\parallel} a\left(\mathbf{U} - \frac{\mathbf{k}_\perp r_\nu}{2\pi}\right). \quad (7)$$

If the first visibility measurement is obtained at $t = 0$, then using Equation (7), the visibility measured at a later time t for a drift scan can be written as

$$\begin{aligned} V_\nu(\mathbf{U}, t) &= \bar{I}_\nu \int \frac{d^3k}{(2\pi)^3} \Delta_{\text{HI}}(\mathbf{k}) \int d^2\theta A(\boldsymbol{\theta}) \\ &\quad \times \exp[ir_\nu(k_\parallel + \mathbf{k}_\perp \cdot (\boldsymbol{\theta} - \Delta\boldsymbol{\theta}(t)))] \exp(-2\pi i \mathbf{U} \cdot \boldsymbol{\theta}) \\ &= \bar{I}_\nu \int \frac{d^3k}{(2\pi)^3} \Delta_{\text{HI}}(\mathbf{k}) e^{ir_\nu k_\parallel} \int d^2\theta A(\boldsymbol{\theta}) \\ &\quad \times \exp\left[-2\pi i \left(\mathbf{U} - \frac{\mathbf{k}_\perp r_\nu}{2\pi}\right) \cdot \boldsymbol{\theta}\right] \\ &\quad \times \exp[-ir_\nu \mathbf{k}_\perp \cdot \Delta\boldsymbol{\theta}(t)]. \end{aligned} \quad (8)$$

Here, $\Delta\boldsymbol{\theta}(t)$ is the angular shift of the intensity pattern in the time period t . Equation (8) follows from Equations (3)–(5) for a changing intensity pattern. In a drift scan, the phase center and the primary beam remain fixed and the only change in the visibility occurs due to the changing intensity pattern of the sky with respect to the phase center.

Our aim is to calculate the correlation between the visibilities measured at two different times (separated by t), by two baselines \mathbf{U} and \mathbf{U}' , and at frequencies ν and ν' . We note that the frequency coverage is far smaller than the central frequency: $|\nu' - \nu| \ll \nu$. This allows us to write $|r'_\nu - r_\nu| \equiv \Delta r_\nu = r'_\nu |\nu' - \nu|$; here, $r'_\nu \equiv |dr_\nu/d\nu|$.

Using Equations (7) and (8), we can write the visibility correlation function as

$$\begin{aligned} \langle V_\nu(\mathbf{U}) V_{\nu'}^*(\mathbf{U}', t) \rangle &= \bar{I}_\nu^2 \int \frac{d^3k}{(2\pi)^3} P_{\text{HI}}(k) e^{ik_\parallel \Delta r_\nu} a \\ &\quad \times \left(\mathbf{U} - \frac{\mathbf{k}_\perp r_\nu}{2\pi}\right) \int d^2\theta A(\boldsymbol{\theta}) \\ &\quad \times \exp\left[-2\pi i \left(\mathbf{U}' - \frac{\mathbf{k}_\perp r_{\nu'}}{2\pi}\right) \cdot \boldsymbol{\theta}\right] \\ &\quad \times \exp[-ir_\nu \mathbf{k}_\perp \cdot \Delta\boldsymbol{\theta}], \end{aligned} \quad (9)$$

where $P_{\text{HI}}(\mathbf{k})$ is the power spectrum of the fluctuations in the HI distribution:

$$\langle \Delta_{\text{HI}}^*(\mathbf{k}) \Delta_{\text{HI}}(\mathbf{k}') \rangle = (2\pi)^3 \delta^3(\mathbf{k} - \mathbf{k}') P_{\text{HI}}(\mathbf{k}), \quad (10)$$

where $\delta^3(x)$ is the Dirac delta function and the angular bracket denotes the ensemble average. The delta function demonstrates that the HI signal is statistically homogeneous. Usually when tracking a fixed region, the ensemble average $\langle \dots \rangle$ (left-hand side of Equation (10)) used to compute the power spectrum is done by averaging over all modes \mathbf{k} for a given $|\mathbf{k}|$. The drift scan strategy enables another possible method to compute the power spectrum for modes in the plane of the sky \mathbf{k}_\perp : averaging over time for a given fixed time difference, Δt , for visibility measurements. We discuss this issue in detail in Section 4. For a statistically homogeneous signal, e.g., the EoR, these two methods yield the same estimate of the power spectrum. However, when the assumption of statistical homogeneity breaks down, e.g., for sparsely distributed point sources, the two methods result in different outcomes. We explicitly make use of this difference in our discussion of point sources in Section 5.

The brightness temperature fluctuations $\Delta_{\text{HI}}(\mathbf{k})$ are a combination of different physical effects, e.g., density fluctuations, ionization inhomogeneities, and density–ionization fraction cross-correlation, e.g., (Furlanetto et al. 2006; Zaldarriaga et al. 2004):

$$\Delta_{\text{HI}} = \beta \delta_b + \beta_x \delta_x + \beta_\alpha \delta_\alpha + \beta_T \delta_T - \delta_{\partial v}. \quad (11)$$

Here, each term refers to the fractional variation in a particular quantity. Thus, δ_b stands for variation in the baryonic density, δ_α for the Ly α coupling coefficient x_α , δ_x for the neutral fraction, δ_T for T_K , and $\delta_{\partial v}$ for the line-of-sight peculiar velocity gradient. β factors are the corresponding expansion coefficients. For further details, we refer the reader to Furlanetto et al. (2006). Throughout this paper, we adopt the theoretical spherically averaged power spectrum (Equation (10)) from Beardsley et al. (2013; Figure 4 of their paper; see also Furlanetto et al. 2006).

The isotropic part of the emission can be calculated as

$$\bar{I}_v = \frac{A_{21} h_P c \bar{n}_{\text{HI}}(z)}{4\pi H(z)}. \quad (12)$$

Here, A_{21} is the Einstein coefficient of the 21 cm HI transition, h_P is the Planck constant, c is the speed of light, and $H(z)$ is the Hubble parameter:

$$H(z) = H_0 [\Omega_{m0}(1+z)^3 + \Omega_{\Lambda 0}]^{1/2}. \quad (13)$$

H_0 is the value of the Hubble constant at the present epoch, $H_0 = 70 \text{ km s}^{-1} \text{ Mpc}^{-1}$, and all of the results are calculated using $\Omega_{m0} = 0.3$ and $\Omega_{\Lambda 0} = 0.7$ (Spergel et al. 2007; Planck Collaboration et al. 2013).

3. DRIFT SCAN VISIBILITY CORRELATION: MWA

We assume the MWA primary beam to compute the visibility correlations (Equation (9)); MWA primary beam can be expressed as

$$A(l, m) = \frac{\sin(\pi L_x l)}{\pi L_x l} \frac{\sin(\pi L_y m)}{\pi L_y m}. \quad (14)$$

Here, L_x and L_y are the sides of an aperture of an MWA tile in units of wavelength with $L_x \approx L_y \approx 2$ and (l, m) being coordinates defined on the sky.

We note that for a dipole array such as MWA, Equation (14) is valid for only a phase center at the zenith. If the phase center is changed (e.g., for tracking a region), then the projected area of the tile decreases which results in a dilation of the primary beam depending on the angular position of the phase center. We neglect this change in the paper and throughout present results for the primary beam given by Equation (14). This assumption alters the signal, the computation of the signal to noise, and the impact of the w term, but does not change our main results. We discuss the implications of this assumption in Appendix B.

Our knowledge of the HI power spectrum (Equation (10)) and the primary beam (Equation (14)) allows us to compute the evolution of the visibility correlations. A detailed formulation of the sky coordinate system for analyzing drift scans from any arbitrary location of an observatory is discussed in Appendix A. We first discuss the fiducial case of a zenith drift scan for an observatory located at the latitude ϕ . The visibility correlation function for this case is derived in Appendix A and is given by Equation (A6):

$$\begin{aligned} \langle V_v(\mathbf{U}) V_v^*(\mathbf{U}', t) \rangle &= \bar{I}_v^2 \int \frac{d^3 k}{(2\pi)^3} P_{\text{HI}}(k) e^{ik_l \Delta r_v} \\ &\quad \times \exp(-i r_v k_{\perp 1} \cos \phi dH) \\ &\quad a \left[\left(u - \frac{r_v k_{\perp 1}}{2\pi} \right), \left(v - \frac{r_v k_{\perp 2}}{2\pi} \right) \right] \\ &\quad a \left[\left(u' - \frac{r_v}{2\pi} (k_{\perp 1} + k_{\perp 2} \sin \phi dH) \right), \right. \\ &\quad \left. \left(v' - \frac{r_v}{2\pi} (k_{\perp 2} - k_{\perp 1} \sin \phi dH) \right) \right]. \quad (15) \end{aligned}$$

Here, dH is the change in hour angle corresponding to the time difference t ; u and v are the components of the baseline vector: $\mathbf{U} = u\hat{u} + v\hat{v}$.

Many generic results, which are common to both the tracking and drift scan cases follow from Equation (15), so we first consider $dH = 0$. (1) The contribution in each visibility correlation from different modes is significant when $k_\perp = 2\pi \mathbf{U}/r_v \pm 1/(\theta_0 r_v)$, where θ_0 is the angular extent of the primary beam. In other words, unless the two baselines being correlated satisfy this condition, the visibilities are decorrelated. For the MWA primary beam, this implies $\mathbf{U} - \mathbf{U}' \gtrsim 0.5$. (2) If the two visibilities being correlated are separated by a non-zero frequency difference $|\nu' - \nu|$, then the signal strength is reduced. We later show that the frequency difference for which the signal drops to half its value: $|\nu' - \nu| \simeq 0.5 \text{ MHz}$. We note here that we assume each visibility measurement to have zero channel width $\Delta\nu = 0$. This is justified because the channel width of MWA is $\Delta\nu \simeq 40 \text{ kHz}$ which is much smaller than the decorrelation width, or $\Delta\nu \ll |\nu' - \nu|$ (Figure 8).

The principle aim of this paper is to analyze the visibility decorrelation in the time domain for a drifting sky.

We show the behavior of the visibility correlation function as a function of time difference for zenith drift assuming the observatory location to be at three different latitudes: 0° (equator), $\pm 30^\circ$, and $\pm 90^\circ$ (pole). The central frequency is chosen to be at $\nu = 129 \text{ MHz}$ corresponding to a redshift of $z = 10$ and $|\nu' - \nu| = 0.0 \text{ MHz}$. (Figure 8). The results are shown for a single baseline vector $\mathbf{U} = (50, 50)$ in Figures 1–3. The envelope

Figure 1. Visibility correlation function as a function of time for the zenith drift from the equator (latitude = 0). Blue and red curves correspond to the real and imaginary parts of the visibility correlation function, respectively. The black curve denotes the envelope of the visibility correlation function. In the figure (and all the subsequent figures that display the visibility correlation), the visibility correlation corresponds to the H1 signal from EoR computed using the power spectrum of Beardsley et al. (2013, Figure 4 of their paper). The central frequency is assumed to be $\nu = 129$ MHz.

(A color version of this figure is available in the online journal.)

of the visibility correlation function shown in the figures is obtained by multiplying Equation (A6) by $\exp(-i2\pi u \cos \phi dH)$ and taking the real part of the resulting expression. This procedure is akin to correcting for the “shift in the phase center.”

It is clear that at the equator, the visibilities measured by the same pair of antennae are correlated for the longest period of time. With increasing latitude of the observer, the correlation timescale decreases and it is at minimum for an observer at the pole (latitude 90°). During a drift scan, the baselines and primary beam remain fixed and the sources move in and out of the primary beam. As we show in Appendix A, the motion of sources during a scan is a combination of translation and rotation depending on the observer location and the field being observed. At the equator, the drift corresponds to pure translation along the east–west axis. From any other location there also exists a rotational component in the zenith drift. The decorrelation timescale is shorter when the rotational component is present. This behavior can be understood from Equation (15). Unless $\phi = 0$, a baseline u receives some contribution from not just $k_{\perp 1}$ but also $k_{\perp 2}$, the mode perpendicular to u in the tracking case. A similar inference holds for v . This results in a decorrelation timescale much shorter than the transit time of the primary beam: $\Delta h \simeq 1/(\sin(\phi)U\theta_0)$, θ_0 is the approximate angular extent of the primary beam. For pure translation, the decorrelation timescale depends only on the transit time of the primary beam.

Of the three fiducial cases we have studied (Figures 1–3), Figure 2 is directly relevant for the location of MWA. It is worthwhile to ask whether or not we could exploit the long time correlation of the equatorial scan using MWA by scanning an equatorial region. In Appendix A, we show that if the phase center is shifted to the equatorial position (along the local meridian) with respect to the new phase center, then the drift is pure translation and the decorrelation due to the rotation can be avoided for this phase center. For a detailed discussion, see Appendix A and Figures 13 and 14.

For an observatory at latitude ϕ , the visibility correlation function with respect to the new phase center can be written as (Equation (A9))

$$\begin{aligned} \langle V_v(\mathbf{U})V_{v'}^*(\mathbf{U}, t) \rangle &= \bar{I}_v^2 \int \frac{d^3k}{(2\pi)^3} P_{\text{H1}}(k) e^{ik_{\parallel} \Delta r_v} \\ &\times \exp(-ir_v k_{\perp 1} \cos(\theta + \phi) dH) \\ &a \left[\left(u - \frac{r_v k_{\perp 1}}{2\pi} \right), \left(v - \frac{r_v k_{\perp 2}}{2\pi} \right) \right] \\ &a \left[\left(u - \frac{r_v}{2\pi} (k_{\perp 1} + k_{\perp 2} \sin(\theta + \phi) dH) \right) \right. \\ &\left. \times \left(v - \frac{r_v}{2\pi} (k_{\perp 2} - k_{\perp 1} \sin(\theta + \phi) dH) \right) \right]. \end{aligned} \quad (16)$$

Here, θ is the angular distance of the new phase center from zenith for an observatory at latitude ϕ . To shift the phase center to the equator, the rotation angle is $\theta = -\phi$. For this phase center, the time dependence of the visibility correlation follows the behavior seen in Figure 1 or, formally, Equation (A6) with $\phi = 0$ yields the same result as Equation (A9) with $\phi = -\theta$. In other words, the two cases—an observatory located at the equator performing a zenith drift scan and an observatory located at some other latitude scanning a region at the equator—are equivalent.

In Figure 5, the time evolution of the visibility correlation function is shown for four different baselines for the equatorial scan.

For an observing frequency of $\nu = 129$ MHz and $\nu' = \nu$ the visibility correlation is $\simeq 10^{-4}$ Jy² for baselines $|\mathbf{U}| \leq 200$. The signal strength decreases with increasing baseline length. Figure 5 also shows that the decorrelation timescale depends only on the size of the primary beam for an equatorial scan.

3.1. Correcting for Rotation

In Figures 2 and 3, one can see that the rotation of sources in the sky plane during the drift scan reduces the timescale of

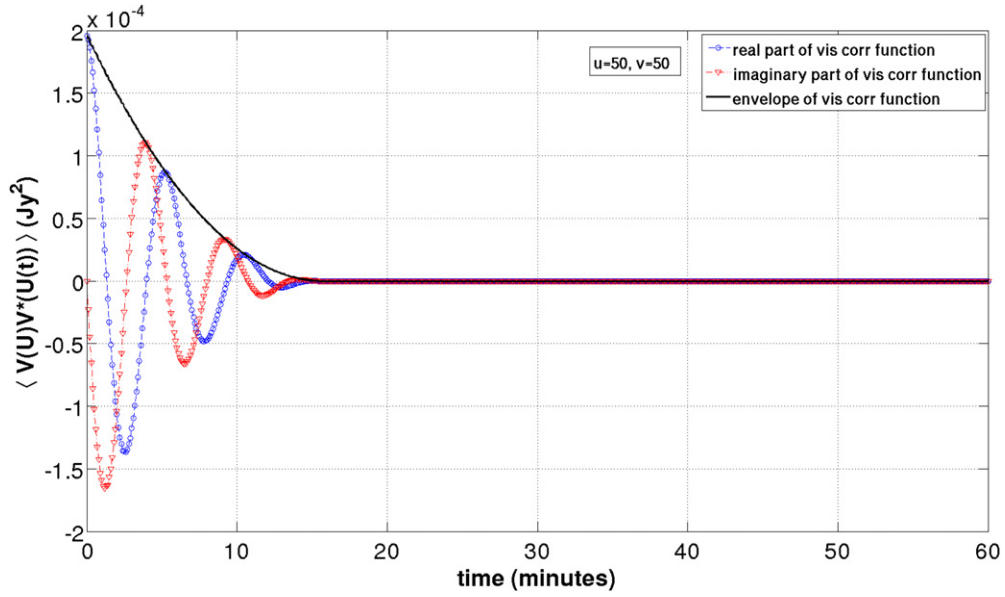

Figure 2. Visibility correlation function as a function of time for the zenith drift from a location with latitude $\pm 30^\circ$. (A color version of this figure is available in the online journal.)

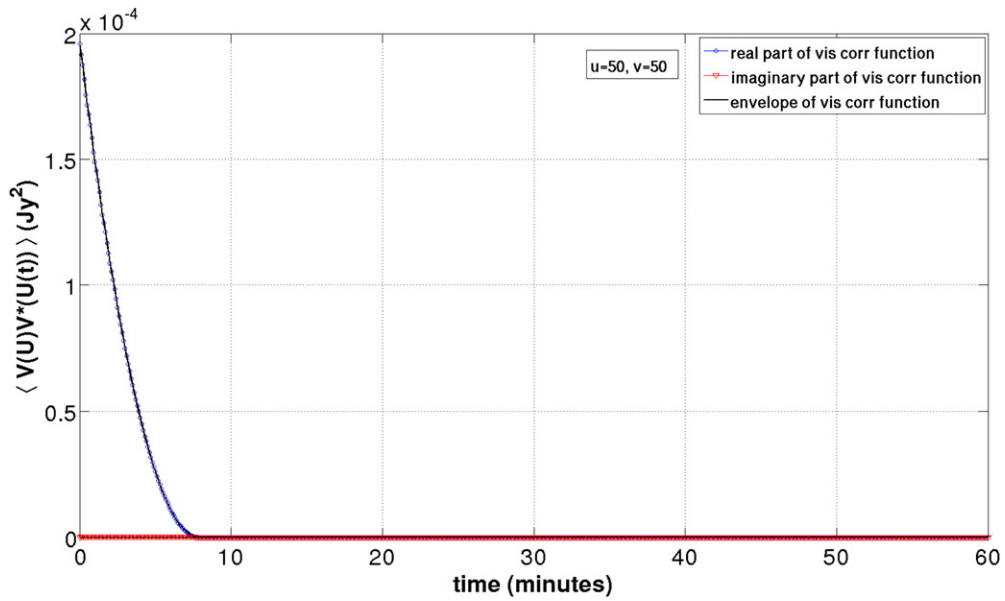

Figure 3. Visibility correlation function as a function of time for the zenith drift from the pole (latitude = $\pm 90^\circ$). (A color version of this figure is available in the online journal.)

decorrelation of the visibility correlation function for a given baseline.

In a drift scan, the phase center remains fixed and therefore there is no change in the values of $\{u, v, w\}$. In other words, the set of baselines during the scan remains the same.

In the preceding (Equation (15) and the discussion following it), we have shown that the visibilities become uncorrelated when $\mathbf{U} - \mathbf{U}' \gtrsim 0.5$ for the MWA primary beam. In the drift scan case, this condition holds if both the visibilities are obtained at the same time. However, Equation (15) can be used to show that this conclusion does not hold for visibilities computed at different times. In particular, we show that $V(\mathbf{U}, t)$ and $V(\mathbf{U}', t')$ can become correlated for $\mathbf{U} \neq \mathbf{U}'$ and $t \neq t'$, if the two baselines are related by a special relation. We derive this relation and illustrate this recorelation with an example.

Two baselines, $\mathbf{U} = (u, v)$ and $\mathbf{U}' = (u', v')$, can be related as

$$\begin{aligned} u' &= u + av + \epsilon, \\ v' &= v - au + \epsilon. \end{aligned}$$

Here, a and ϵ correspond to rotation and translation, respectively. These parameters can be solved to give

$$\begin{aligned} a &= \frac{\Delta u - \Delta v}{u + v}, \\ \epsilon &= \frac{u\Delta u + v\Delta v}{u + v}. \end{aligned}$$

Here, $\Delta\mathbf{U} = \mathbf{U} - \mathbf{U}'$.

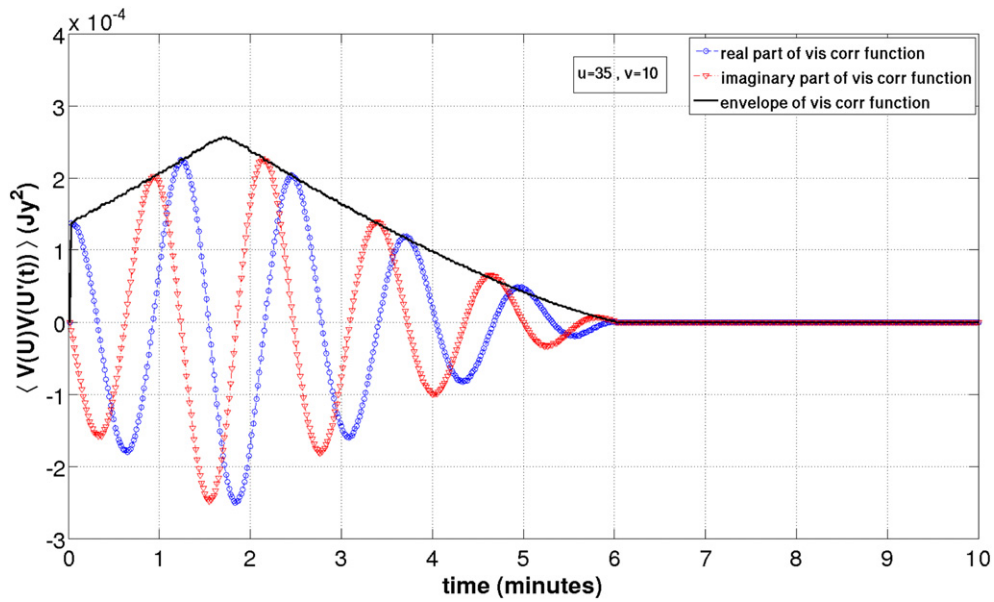

Figure 5. Visibility correlation function as a function of time for visibilities with different baselines. The drift scan corresponds to a zenith scan for a latitude of 30° .

(A color version of this figure is available in the online journal.)

It can be shown that for two baselines with $\varepsilon \geq 0.5$, the signal becomes uncorrelated and cannot be re-correlated at any other time. This also means that two baselines with different lengths $(u^2 + v^2)^{1/2}$ remain uncorrelated during the drift scan. However, many baselines in an experiment such as MWA have nearly the same lengths and are related to each other by a near-pure rotation denoted by the parameter a . We can show that such baselines correlate with each other during the drift scan if $a = \sin(\phi)dH$. In other words, if a visibility is measured at a time $t = 0$ for a baseline \mathbf{U} , then this measurement will correlate with another measurement for a baseline \mathbf{U}' at a time corresponding to dH if the two baselines are related by a near-pure rotation with the corresponding rotation parameter $a = \sin(\phi)dH$. We note that this correlation can occur just once during a long scan and the timescale over which the baselines remain correlated corresponds to the decorrelation time for a given $|\mathbf{U}|$.

We illustrate this re-correlation for a baseline $\mathbf{U} = (35, 10)$. The other baseline, $\mathbf{U}' = (34.8, 10.7)$, corresponds to the parameters $a = -0.02$ and $\varepsilon = 0$. The visibility correlation function is shown as a function of time in Figure 5.

In Figure 6, we show the timescale over which the visibility correlation falls to half its value for $\Delta t = 0$ (e.g., Figure 2); this timescale is observed to fall as roughly the inverse of the baseline length, in agreement with the discussion in the previous subsection.

The re-correlation of baselines allows us to partially recover the loss of signal due to decorrelation. However, the set of baselines is fixed for a drift scan strategy, and therefore the range of baselines which correlate at different times must be present in the initial set. For the MWA, we estimate that for a zenith scan at the latitude of the telescope, there are nearly 120 such pairs which satisfy $\varepsilon \leq 0.5$ and $a \leq 0.3$ for $|\mathbf{U}| \simeq 20\text{--}70$.

Figure 6. Time difference Δt at which the visibility correlation falls to half its value, as a function of baseline, for an overhead scan at the location of MWA ($\phi = -26.7$). (A color version of this figure is available in the online journal.)

(As noted below, the total number of baselines in a zenith snapshot observation for MWA is 2735 in the range $|\mathbf{U}| \simeq 20\text{--}230$.) These baselines will retain at least half the signal and would correlate within a correlation timescale of less than 2 hr.

4. ERROR ON VISIBILITY CORRELATION

The error on the visibility correlation is

$$\sigma^2(U) = \langle V_v(\mathbf{U})V_v(\mathbf{U})V_{v'}(\mathbf{U}', t)V_{v'}(\mathbf{U}', t) \rangle - \langle V_v(\mathbf{U})V_{v'}(\mathbf{U}', t) \rangle^2. \quad (17)$$

Here, $U \equiv |\mathbf{U}|$ and the averages are taken over many different variables: the noise is uncorrelated for different frequencies, baselines, and times. However, the signal could be correlated in all three domains. We average over all the pairs in the three domains and finally over all the pairs for baselines in the range U and $U + \Delta U$ to compute an estimate for a wider bin ΔU . The measured visibilities and their correlations receive contributions from detector noise, the H I signal, and the foreground. When only visibilities at two times (or frequencies/baselines) are correlated, as we assume here, the $\langle VV \rangle$ does not receive any contribution from detector noise and therefore constitutes an unbiased estimator of the signal. In this case, only the first term in the equation above contributes to the error estimate; denoting the sky noise as N_v , we get

$$\sigma^2(U) = \frac{1}{N_{\text{tot}}} \langle N_v(\mathbf{U})N_v^*(\mathbf{U}) \rangle^2. \quad (18)$$

Here, N_{tot} are all the baseline pairs in the range U and $U + \Delta U$ in the 3D cube and the time domain.

The average noise autocorrelation for each independent correlation of visibilities is

$$\langle N_v(\mathbf{U})N_v^*(\mathbf{U}) \rangle = \left[\frac{T_{\text{sys}}}{K\sqrt{\Delta\nu\Delta t}} \right]^2, \quad (19)$$

where T_{sys} is the system temperature, $\Delta\nu$ is the channel width, K is the antenna gain, and Δt is the integration time. Here, Δt and $\Delta\nu$ could be arbitrarily small; in particular, we require the

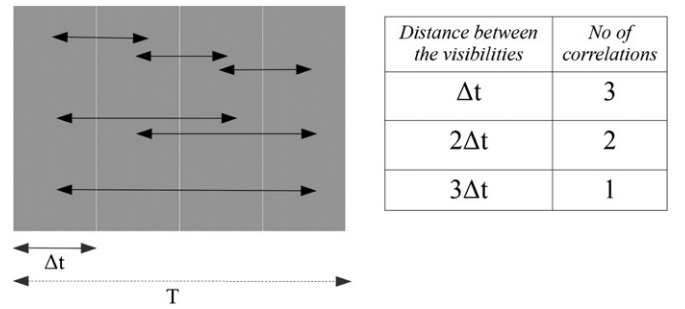

Figure 7. Illustration showing the number of possible correlations for total observing time T and integration time Δt with $T/\Delta t = 4$, or four visibility measurements. The number of correlations between visibilities with time difference Δt is four, for time difference $2\Delta t$ the number is three, etc.

bandwidth and integration time to be much smaller than the frequency and time coherence of the signal (Figures 1–3 and 6). N_{tot} is determined from the correlation timescale in time and frequency domains and its computation is discussed below. We cross-correlate all visibility pairs for a given time difference and the frequency difference for the equatorial scan case where we assume $\mathbf{U} = \mathbf{U}'$; we also include the impact of recorrelating baselines (Section 3.1) in the overhead scan case (Figure 2).

For a given total observing time T and integration time Δt , there exists $n = T/\Delta t$ visibility measurements. Among these n measurements, the number of possible independent correlations between visibilities $i\Delta t$ time apart (where $i = 1, 2, \dots, n$) is $(n - i)$ as explained in Figure 7. Thus, the average noise correlation for a given baseline vector \mathbf{U} with visibilities separated by times $i\Delta t$ is

$$\sigma_i(\mathbf{U}) = \langle N_v(\mathbf{U})N_v^*(\mathbf{U}(i\Delta t)) \rangle = \frac{1}{(n - i)} \left[\frac{T_{\text{sys}}}{K\sqrt{\Delta\nu\Delta t}} \right]^2, \quad (20)$$

for any frequency channel.

Figure 4 shows that the signal $\sqrt{\langle V_v(\mathbf{U})V_{v'}^*(\mathbf{U}', t) \rangle}$ decorrelates with increasing time difference between the visibilities. This means that not all pairs contribute equally to the signal to noise of the measurement. To obtain an estimator which gives

Figure 8. Left: the decorrelation of the visibility correlation of the H I signal as a function of the frequency separation (see the caption of Figure 1 and the discussion in Section 3 for details). The right panel denotes the bandwidth for a given \mathbf{U} at which the signal drops to half of its maximum at different times.

(A color version of this figure is available in the online journal.)

suitable weight to all of the pairs, we define

$$w_i(\mathbf{U}) = \frac{\langle V_\nu(\mathbf{U})V_\nu^*(\mathbf{U}(t=0)) \rangle}{\langle V_\nu(\mathbf{U})V_\nu^*(\mathbf{U}(t=i\Delta t)) \rangle}. \quad (21)$$

This allows us to write the following optimal estimator for computing the noise on the visibility measurement:

$$\frac{1}{(\sigma_U^2)^2} = \sum_{i=1}^n \frac{1}{(\sigma_i^2 w_i)^2}. \quad (22)$$

We neglect the effect of partial coherence of baselines at the initial time; this assumption slightly underestimates the sensitivity and is further discussed in the next subsection. We do not include sampling variance in our error estimates.

The preceding discussion is valid for visibility measurements for a given frequency. The H I signal is correlated across the frequency space (Figure 8). The figure shows the behavior of the H I signal as a function of $|\nu' - \nu|$ for different baselines. The right panel of the figure displays the frequency difference at which the signal falls to half of the maximum ($|\nu' - \nu| = 0$) for different times. We treat the correlation across the frequency space using the same method described above for the time correlation.

In Figure 9, we show the expected noise on the visibility correlation for many different cases. For all the cases, we assume the following parameters for the MWA: observing frequency $\nu = 129$ MHz, system temperature $T_{\text{sys}} = 440$ K, and the effective area of each tile $A_{\text{eff}} = 16$ m 2 .

Case I. We consider continuous equatorial drift scans with durations of 2 and 4 hr. One way to repeat the scan for the same phase center is to shift the phase center to the same position after the end of the scan; this results in a change of UV coverage. We consider the simpler case when the UV coverage and the phase center remain the same for subsequent scans. This corresponds to the same region of sky being observed on different days. In Figure 9, we show the results for 900 hr of integration in this mode.

As the signal strength is greater for shorter baselines (Figure 4), we consider only baselines in the range $\mathbf{U} = 20$ –230. We take bins of size $\mathbf{U} \simeq 10$ and show the noise correlation for this range of baselines in Figure 9. MWA has 2735 baselines in

this range for a snap-shot observation. Using the information, the rms noise for this mode is $\sigma \simeq 16$ (mJy) 2 and $\sigma \simeq 21$ (mJy) 2 for 2 and 4 hr scans, respectively. We note that since the visibility correlation function drops significantly after roughly 1 hr (Figure 1), the noise is expected to increase for longer drift scans.

Case II. Here, we consider an overhead drift scan at the location of MWA. The correlation timescale is shorter for such scans compared to the equatorial scan (Figure 2). In Figure 6, we show the timescale over which the correlation falls by half as a function of the baseline length.

As noted above, many baselines are re-correlated as the time progresses (Figure 5). More than 5%–10% of all the baselines in the range $|\mathbf{U}| = 20$ –100 are re-correlated with $\epsilon \leq 0.5$ in less than 2 hr. We include these baselines in the noise computation. As compared to Case I, the noise is higher in this case as the correlation time is shorter.

Case III. For comparison with the drift scan cases, we also compute the error in the visibility correlation for the tracking case. We consider two cases: 2 and 6 hr of continuous tracking of a region across the zenith (± 1 hr and ± 3 hr) at the location of MWA ($\phi = -26.7$). The results are shown in Figure 9. We discuss the results in detail in the next subsection.

4.1. Drift versus Tracking Mode

In any interferometric experiment to determine the EoR signal, the rms noise on the visibility correlation is bounded by

$$\sigma_{\min} = \left(\frac{1}{N_b} \right)^{1/2} \left(\frac{T_{\text{sys}} K}{\sqrt{\Delta\nu T}} \right)^2, \quad (23)$$

$$\sigma_{\max} = \left(\frac{\Delta t}{N_b T} \right)^{1/2} \left(\frac{T_{\text{sys}} K}{\sqrt{\Delta\nu \Delta t}} \right)^2. \quad (24)$$

Here, T is the total time of integration and Δt is the integration time for a single visibility measurement. For the sake of the discussion, $\Delta\nu$, the channel width, is assumed to be fixed. $N_b = n(n-1)/2$ is the total number of baselines for any measurement with n antenna elements. σ_{\min} gives the rms noise if all of the visibilities are coherently added and σ_{\max}

Figure 9. Error on visibility correlation as a function of baseline length: blue (triangle) and red (square) points refer to 2 and 4 hr equatorial drift scans, respectively. Black (inverted triangle) points refer to 2 hr zenith drift scan at the location of MWA. The green (circle) and pink (rotated triangle) points show the expected error for 2 and 6 hr tracking runs (for ± 3 and ± 1 hr continuous overhead tracking at MWA location). In all of the cases, the total integration is 900 hr. The EoR signal is designated by the dashed brown line.

(A color version of this figure is available in the online journal.)

corresponds to the case when the visibility correlations are incoherently added. For the 128 tile MWA, the rms lies between these two extremes for both the tracking mode and drift scans. As noted above, we neglect partially coherent baselines for computing the sensitivity for drift scans; this assumption is consistent with Equation (23).

The process of decoherence occurs differently for the tracking and drift scan modes. For drift scans, it is the decorrelation of the EoR signal at different times, as described in detail in the previous sections. In the tracking case, the process of tracking a given region rotates the visibility vector \mathbf{U} ; the correlation between visibility measurements at different values of \mathbf{U} decreases; from Equation (9), we can show that the decorrelation scale $\Delta U \simeq \theta_0^{-1} \simeq 0.5$ has a very weak dependence on the value of \mathbf{U} . For our computation, we take the pixel size $\{\Delta U, \Delta V\} = \{0.5, 0.5\}$. The frequency decorrelation for the tracking case is taken from Figure 8.

The results for 2 and 6 hr tracking runs (with zenith at the location of MWA) are shown for 900 hr of integration in Figure 9. We note here that we do not present the results for the equatorial tracking run, as the sensitivity in this case shows only a marginal improvement over the zenith tracking runs shown in Figure 9. As the figure shows, the drift scan generally gives lower noise on the visibility correlation for up to 4 hr of drift scans.

This result can be understood as follows. As an extreme case, one could drift for a very short duration each day, such that there is no decorrelation, and continue similar observations on the same field such that all the visibility measurements are coherently added. In this case, the rms for the drift case would approach σ_{\min} , which is not possible to achieve in the tracking case because the process of tracking would always decorrelate the signal. The relevant question is as follows: what is the timescale for drift scans such that this advantage of lower noise is not lost? We show that this advantage holds even

for 4 hr drift scans. In the drift scan case, the decorrelation timescale is $\simeq 1$ hr. In the tracking cases, different baselines decorrelate in the process of tracking a region of the sky, but some baselines revisit the same pixel in this process. For instance, for the 6 hr tracking run shown in Figure 9, the average integration time of a pixel in the range $|\mathbf{U}| = 20\text{--}30$ is roughly 15 minutes with the total number of uncorrelated pixels $\simeq 4700$.

It should be underlined that apart from other assumptions delineated in the previous subsection, the lower noise in the drift scan is also based on the assumption that the system temperature does not change over the scan. Also, an additional disadvantage in the drift scan case is that there are smaller numbers of visibility measurements available at any given time for imaging compared to the tracking case where the UV coverage is better.

5. STATISTICAL HOMOGENEITY OF EoR SIGNAL AND FOREGROUND EXTRACTION

Unlike the tracking case, the drift scans explicitly exploit the statistical homogeneity of the EoR signal: cross correlation of the signal at different times only depends on the time difference. More precisely, the power spectrum of the EoR signal for any phase center is drawn from a random density field with the same average power spectrum. This assumption may or may not hold for foregrounds. For instance, if faint point sources are distributed homogeneously across the sky with the same flux distribution, then they will also closely correspond to a statistically homogeneous field in two dimensions. However, most other foregrounds, e.g., bright point sources or galactic foregrounds, will explicitly break the statistical homogeneity of the sky, and therefore would be potentially distinguishable from the EoR signal.

We illustrate this concept with the point source distribution on the sky. For a point source distribution with fluxes $\{F_i\}$, the

Figure 10. Envelope of the visibility correlation function (normalized arbitrarily) as a function of time difference for three different cases described in the text. (A color version of this figure is available in the online journal.)

visibility can be written as

$$V(\mathbf{U}) = \sum_j \exp(2\pi i \mathbf{U} \cdot \theta_j(t)) F_j A(\theta_j(t)). \quad (25)$$

Here, $\theta_i(t)$ correspond to the time varying position of point sources on the sky with respect to the fixed phase center. $A(\theta_i(t))$ gives the primary beam in the same coordinate system. The visibility correlation separated by time Δt is

$$\begin{aligned} \langle V(\mathbf{U}, t) V^*(\mathbf{U}, t + \Delta t) \rangle = & \left\langle \sum_k \sum_j \exp(2\pi i \mathbf{U} \cdot (\theta_j - \theta_k)) \right. \\ & \left. \times F_j F_k A(\theta_j(t)) A(\theta_k(t + \Delta t)) \right\rangle. \end{aligned} \quad (26)$$

Here, the averaging process $\langle \dots \rangle$ is over all the pairs for a given Δt during the drift scan. This averaging procedure leads to substantially different results for the EoR signal and the foregrounds: the EoR signal is statistically homogeneous and therefore any cross-correlation depends only on Δt . For each Δt , the EoR signal gives a realization of the density field with a given fixed power spectrum (Equation (9)). However, the foregrounds might not share this property and might show explicit dependence on not only the time difference but also the time period of the scan. This gives at least two different methods of extracting foregrounds. (1) Correlation pairs of a given Δt can be used to fit the time variation expected of foregrounds. While the EoR signal will show fluctuations about a given mean, the foregrounds will show more secular time variation which can potentially be subtracted. (2) Direct comparison of the averaged correlation function should also reveal the difference between the two cases. We demonstrate the procedure with method (2) here.

For the MWA primary beam, we consider three different source counts: 10, 30, and 50 sources. At the beginning of the drift scan, the sources are randomly distributed within $\pm 15^\circ$ from the center of the primary beam with an hour angle between -3 to $+3$ hr. The fluxes are drawn from a uniform distribution with values between 0 and 1 Jy. The visibility correlation functions for all these cases for $\mathbf{U} = (50, 50)$ are shown in Figure 10.

As predicted in the preceding discussion, Figure 10 shows that the visibility correlation function for point sources is

substantially different compared to the HI signal due to the statistical inhomogeneity of the point source distribution. This can be used to subtract the contribution of bright point sources from the measured visibility itself.

6. CONCLUSIONS

The main goal of this paper is to investigate the potential of the drift scan technique in estimating the EoR signal. Drift scans introduce a new dimension to the issue: the correlation between visibilities in time domain. Here we present a formalism which uses this correlation to determine the EoR signal.

The important results are as follows:

1. The visibilities measured at different times by the same pair of antennas in a drift scan are correlated for up to 1 hr for equatorial scans (Figure 1). The decorrelation timescale depends on the choice of phase center. It is maximum for an equatorial zenith drift or for equatorial phase center. For such scans, the decorrelation timescale is independent of the baseline length. For other scans the decorrelation timescale is shorter and depends on the baseline vector (Figures 2 and 3). However, a fraction of these baselines correlate with other baselines at a different time (Figure 5).
2. We compute the expected error on the visibility correlation for drift scans and compare with the expected noise in the tracking case (Figure 9). Our results show that the noise is comparable in the two cases and the drift scan might lead to a superior signal to noise for equatorial scans.
3. The drift scan technique also opens another avenue for the extraction and subtraction of foregrounds: the EoR signal is statistically homogeneous while the foregrounds might not share this property. We investigate the potential of this possibility using a set of bright point sources (Figure 10).

Our results suggest that drift scans might provide a viable, and potentially superior, method for extracting the EoR signal. In this paper, we present mainly analytic results to make our case. In the future, we hope to return to this issue with numerical simulations and direct application of our method to the MWA data.

APPENDIX A

COORDINATE SYSTEM FOR DRIFT SCANS

The position vector in the sky θ can be expressed in terms of two direction cosines l and m . These direction cosines are defined with respect to a local coordinate system when phase center is at zenith as explained in Figure 11 (e.g., Christiansen & Hogbom 1969):

$$\begin{aligned} l &= \cos \delta \sin H, \\ m &= \cos \delta \cos H \sin \phi - \sin \delta \cos \phi, \\ n &= \cos \delta \cos H \cos \phi + \sin \delta \sin \phi. \end{aligned} \quad (\text{A1})$$

Here δ and H are the declination and hour angle of any source; and ϕ is the latitude of the place of observation.

Using this coordinate system the second integral in visibility expression Equation (8) takes the form

$$\int dldmA(l, m) \exp \left[-2\pi i \left\{ \left(u - \frac{k_{\perp 1} r_v}{2\pi} \right) l + \left(v - \frac{k_{\perp 2} r_v}{2\pi} \right) m \right\} \right] \exp [-ir_v(k_{\perp 1} \Delta l + k_{\perp 2} \Delta m)]. \quad (\text{A2})$$

Here Δl and Δm are the change in l and m with time or hour angle as in sky drift only hour angle changes with time for a fixed declination. $k_{\perp 1}$ and $k_{\perp 2}$ are the two components of \mathbf{k}_{\perp} along l and m on the sky plane. Using Equation (A1) and the condition $l^2 + m^2 + n^2 = 1$ we can expand in the first order to compute the changes in relevant quantities:

$$\Delta l = (m \sin \phi + n \cos \phi) dH, \quad \Delta m = -(l \sin \phi) dH. \quad (\text{A3})$$

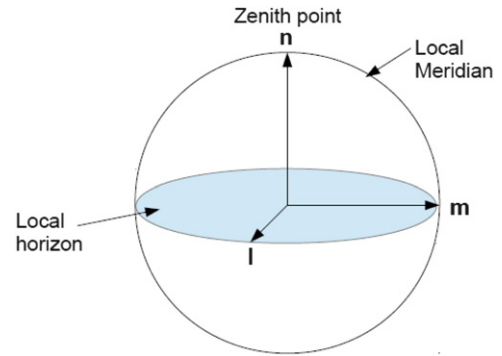

Figure 11. l, m, n coordinates defined for a phase center at zenith. (A color version of this figure is available in the online journal.)

Here dH is the change in hour angle in time interval t . We can further simplify the expression by using $n \simeq 1$. The two approximations used above are: $1/2(l^2 + m^2) \ll 1$ and $dh \ll 1$. Both these approximations are valid for the MWA primary beam (Equation (14)) and for a few hours of correlation time. Thus the second integral (Equation (A1)) becomes

$$\begin{aligned} & \exp(-ir_v k_{\perp 1} \cos \phi dH) \int dldmA(l, m) \\ & \times \exp \left[-2\pi i \left\{ \left(u - \frac{r_v}{2\pi} (k_{\perp 1} + k_{\perp 2} \sin \phi dH) \right) l + \left(v - \frac{r_v}{2\pi} (k_{\perp 2} - k_{\perp 1} \sin \phi dH) \right) m \right\} \right]. \end{aligned}$$

It can be expressed in terms of the Fourier transform of the primary beam:

$$\begin{aligned} & \exp(-ir_v k_{\perp 1} \cos \phi dH) a \left[\left(u - \frac{r_v}{2\pi} (k_{\perp 1} + k_{\perp 2} \sin \phi dH) \right), \right. \\ & \left. \left(v - \frac{r_v}{2\pi} (k_{\perp 2} - k_{\perp 1} \sin \phi dH) \right) \right]. \end{aligned} \quad (\text{A4})$$

With this the visibility measured at a later time t becomes

$$\begin{aligned} V_v(\mathbf{U}, t) &= \bar{I}_v \int \frac{d^3 k}{(2\pi)^3} \Delta_{H1}(\mathbf{k}) e^{ir_v k_{\parallel}} \exp(-ir_v k_{\perp 1} \cos \phi dH) \\ & a \left[\left(u - \frac{r_v}{2\pi} (k_{\perp 1} + k_{\perp 2} \sin \phi dH) \right), \right. \\ & \left. \left(v - \frac{r_v}{2\pi} (k_{\perp 2} - k_{\perp 1} \sin \phi dH) \right) \right]. \end{aligned} \quad (\text{A5})$$

Correlating this with the visibility measured at $t = 0$ (Equation (7)) gives

$$\begin{aligned} \langle V_v(\mathbf{U}) V_v^*(\mathbf{U}', t) \rangle &= \bar{I}_v^2 \int \frac{d^3 k}{(2\pi)^3} P_{H1}(k) e^{ik_{\parallel} \Delta r_v} \\ & \times \exp(-ir_v k_{\perp 1} \cos \phi dH) \\ & a \left[\left(u - \frac{r_v k_{\perp 1}}{2\pi} \right), \left(v - \frac{r_v k_{\perp 2}}{2\pi} \right) \right] \\ & a \left[\left(u' - \frac{r_v}{2\pi} (k_{\perp 1} + k_{\perp 2} \sin \phi dH) \right), \right. \\ & \left. \left(v' - \frac{r_v}{2\pi} (k_{\perp 2} - k_{\perp 1} \sin \phi dH) \right) \right]. \end{aligned} \quad (\text{A6})$$

Equation (A6) and the discussion in this section allows us to interpret Figures 1–3. If $\phi = 0$, or the observatory is

Figure 12. Illustration of new lmn coordinate system.
(A color version of this figure is available in the online journal.)

Figure 13. Source trajectories in lmn coordinate system (phase center at zenith) for an observer at latitude -30° .
(A color version of this figure is available in the online journal.)

located at the equator, then the trajectory of sources around the phase center in a drift scan is pure translation; for any non-zero ϕ the motion is a combination of rotation and translation (Equation (A3)). For pure translation, one obtains Figure 1, or the decorrelation timescale is determined solely by the extent of the primary beam. The decorrelation timescale is shorter for any non-zero ϕ (Figures 2, 3, and 6) and depends on the baseline, as already noted in Section 3.

MWA is not located at the equator but we show below that, even for an observatory not located at the equator, if the phase center is shifted to an equatorial position one can remove the rotation of sources in the coordinate system constructed for the new phase center. For simplicity we construct a coordinate system around the local meridian but our conclusions remain valid for any phase center along the equator.

For a phase center that lies on the local meridian with angular separation θ from the zenith at the observatory (Figure 12), the new set of coordinate system is obtained by a single rotation θ of the m and n axes about l as shown in the Figure 12.

Thus the new coordinates can be expressed as

$$\begin{pmatrix} l' \\ m' \\ n' \end{pmatrix} = \begin{pmatrix} 1 & 0 & 0 \\ 0 & \cos \theta & \sin \theta \\ 0 & -\sin \theta & \cos \theta \end{pmatrix} \begin{pmatrix} l \\ m \\ n \end{pmatrix}. \quad (\text{A7})$$

Substituting l, m, n values from Equation (A1) we get

$$\begin{aligned} l' &= \cos \delta \sin H, \\ m' &= \cos \delta \cos H \sin(\theta + \phi) - \sin \delta \cos(\theta + \phi), \\ n' &= \cos \delta \cos H \cos(\theta + \phi) + \sin \delta \sin(\theta + \phi). \end{aligned} \quad (\text{A8})$$

We illustrate the difference between the two coordinate systems with a set of point sources with given initial positions

Figure 14. Source trajectories in $l'm'n'$ coordinate system (phase center shifted to equator) for the same observer as in Figure 13.
(A color version of this figure is available in the online journal.)

(hour angle and declination) and compute source trajectories in both lmn and $l'm'n'$ coordinates. The unprimed coordinates are for a zenith scan at the location of the observatory. The primed coordinates are for a phase center which is at equatorial position at the meridian. In this case, for an observer situated at latitude ϕ , the angle of rotation $\theta = -\phi$. For instance for an observer at latitude $\phi = 30^\circ\text{N}$, rotation angle is $\theta = -30^\circ$.

Ten sources are chosen randomly within declination $\pm 10^\circ$ of the center of the primary beam and all with initial hour angle -2 hr. The sources are allowed to drift past the primary beam for a total drift duration of 4 hr. The trajectories are shown Figures 13 and 14. A contour plot of the primary beam is also included in each figure.

Using the new primed coordinate system instead of the previous one with phase center at zenith at the observatory, one obtains the expression for the visibility correlation function as

$$\begin{aligned} \langle V_v(\mathbf{U}) V_v^*(\mathbf{U}', t) \rangle &= \bar{I}_v^2 \int \frac{d^3 k}{(2\pi)^3} P_{H_1}(k) e^{ik_{\parallel} \Delta r_v} \\ &\quad \times \exp(-ir_v k_{\perp 1} \cos(\theta + \phi) dH) \\ &\quad a \left[\left(u - \frac{r_v k_{\perp 1}}{2\pi} \right), \left(v - \frac{r_v k_{\perp 2}}{2\pi} \right) \right] \\ &\quad a \left[\left(u' - \frac{r_v}{2\pi} (k_{\perp 1} + k_{\perp 2} \sin(\theta + \phi) dH) \right) \right. \\ &\quad \left. \times \left(v' - \frac{r_v}{2\pi} (k_{\perp 2} - k_{\perp 1} \sin(\theta + \phi) dH) \right) \right]. \end{aligned} \quad (\text{A9})$$

Equations (A9) and (A6) are the main results of the paper.

APPENDIX B

w TERM AND OTHER ASSUMPTIONS

We have neglected the w term in our formalism. In this section, we attempt to assess the possible impact of this term. The inclusion of the w term changes Equation (1) to

$$V_v(\mathbf{U}) = \int A(\theta) I_v(\theta) e^{-i2\pi(ul+vm+w(1-n))} d\Omega. \quad (\text{B1})$$

Here $n = (1 - l^2 - m^2)^{1/2}$. The solid angle $d\Omega = dl dm / (1 - n)$. For MWA primary beam we can use the flat sky approximation $1/2(l^2 + m^2) \ll 1$ (Figures 13 and 14). As noted above this approximation might break down when regions close to the

horizon are tracked. However, it remains a good approximation for zenith drift scan. We also make the simplifying assumption that the primary beam is a Gaussian: $A(l, m) = \exp(-(l^2 + m^2)/\theta_0^2)$; this allows us to make analytic estimates.

From Equation (A9), including the w term, the visibility at any time t can be written as (we assume $\theta = 0$, or a zenith scan):

$$\begin{aligned} V_v(u, v, w; t) = & \bar{I}_v \int \frac{d^3k}{(2\pi)^3} \Delta_{\text{HI}}(\mathbf{k}) e^{ir_v k_{\parallel}} \\ & \times \exp(-ir_v k_{\perp 1} \cos \phi dH) \\ & \times \int dl dm A(l, m) \exp \left[-2\pi i \left\{ \left(u - \frac{r_v}{2\pi} \right. \right. \right. \\ & \times (k_{\perp 1} + k_{\perp 2} \sin \phi dH) \Big) l \\ & \left. \left. \left. + \left(v - \frac{r_v}{2\pi} (k_{\perp 2} - k_{\perp 1} \sin \phi dH) \right) m - \frac{1}{2} w (l^2 + m^2) \right\} \right]. \end{aligned}$$

For a Gaussian primary beam, the integral over angles can be computed analytically by extending the integration limits from $-\infty$ to ∞ which is permissible as the primary beam has a narrow support. This gives us

$$\begin{aligned} V_v(u, v, w; t) = & \bar{I}_v \int \frac{d^3k}{(2\pi)^3} \Delta_{\text{HI}}(\mathbf{k}) e^{ir_v k_{\parallel}} \\ & \times \exp(-ir_v k_{\perp 1} \cos \phi dH) \\ & \times \left(\frac{\pi}{q} \right) \exp(-a_1^2/(4q)) \exp(-a_2^2/(4q)). \end{aligned} \quad (\text{B2})$$

Here, for an zenith scan, $a_1 = [u - (r_v/2\pi)(k_{\perp 1} + k_{\perp 2} \sin \phi dH)]$ and $a_2 = [v - (r_v/2\pi)(k_{\perp 2} - k_{\perp 1} \sin \phi dH)]$ and $q = (1/\theta_0^2 - i w \pi)$. Equation (B2) shows that the main impact of the w term is to make the primary beam term complex. The w term results in the information being distributed differently between the real and imaginary part of the visibility. If we consider just the real part of the visibility, the primary beam appears to shrink by a factor: $1/(1 + \pi^2 w^2 \theta_0^4)$, which is indicative of the well-known result that the presence of the w term decreases the angular area that can be imaged.

The visibility correlation is computed to be

$$\begin{aligned} \langle V_v(u, v, w) V_v^*(u', v', w'; t) \rangle = & \bar{I}_v^2 \int \frac{d^3k}{(2\pi)^3} P_{\text{HI}}(k) e^{ik_{\parallel} \Delta r_v} \\ & \times \exp(-ir_v k_{\perp 1} \cos(\phi) dH) \\ & \times \left(\frac{\pi}{p} \right) \left(\frac{\pi}{p'} \right) \exp\left(-\frac{a_1^2}{4p}\right) \exp\left(-\frac{a_2^2}{4p}\right) \\ & \times \exp\left(-\frac{a_3^2}{4p'}\right) \exp\left(-\frac{a_4^2}{4p'}\right). \end{aligned} \quad (\text{B3})$$

Here $a_3 = [u' - (r_v/2\pi)k_{\perp 1}]$, $a_4 = [v' - (r_v/2\pi)k_{\perp 2}]$, $p = (1/\theta_0^2 + \theta_0^2 w^2 \pi^2)$, $p' = (1/\theta_0^2 + \theta_0^2 w'^2 \pi^2)$. For $w, w' = 0$, Equation (B3) reduces to Equation (15) for a Gaussian beam. One of the important conclusions of Equation (B3) is that the inclusion of the w term does not alter the nature of coherence of visibilities over time. The main impact of the w term is to

effectively shrink the size of primary beam from θ_0^2 to $1/p$. It can be shown that the visibility correlation scales as the primary beam (e.g., Equations (11)–(13) of Bharadwaj & Sethi 2001), and therefore, for non-zero w , the correlation of raw visibilities results in a decrease in the signal. We note that for near coplanar array such as MWA, this effect is negligible for zenith drift scans.

An important application of Equation (B3) occurs in computing the sensitivity of the detection of the HI signal in the tracking mode ($dH = 0$ for the tracking case). As described in Section 4.1, we assume all the visibilities in a narrow range of baselines to be coherent. However, these visibilities are computed at different times while tracking a region and therefore correspond to different values of w . Equation (B3) allows us to compute the loss of this correlation.

The impact of the w term can be tackled using well-known algorithms based on facet imaging or w -projection (for details see, e.g., Cornwell et al. 2008). In other words, if raw visibilities are correlated then we expect a small loss of signal. However, if the raw visibilities are first treated by facet imaging, then the impact of the w term can be reduced for either drift scans and tracking. We hope to return to this issue in future work.

Throughout this paper we assume the primary beam to be given by Equation (14). As noted above, this assumption is only valid for a phase center fixed to the zenith at the location of MWA. If the phase center is moved to a point on the sky that makes an angle δ with the zenith then the projected area in that direction scales as $\cos \delta$ and the primary beam scales as $1/\cos \delta$. As noted above the HI signal scales as the primary beam. The antenna gain K (Equation (19)) scales as the effective area of the telescope or as the inverse of the primary beam. As the error on the HI visibility correlation scales as the square of the antenna gain (Equation (19)), the signal to noise for the detection of the HI signal degrades as $\propto \cos \delta$. For instance, an equatorial drift scan would result in a loss of a factor of roughly 1.2 in signal to noise as compared to the zenith scan. This loss of sensitivity is severer for the tracking case if regions far away from the zenith are tracked. We note that our conclusions based on the cases considered in this paper are not altered by this loss.
